Many economic and causal parameters depend on nonparametric or high dimensional first steps. We give a general construction of locally robust/orthogonal moment functions for GMM, where first steps have no effect, locally, on average moment functions. Using these orthogonal moments reduces model selection and regularization bias, as is important in many applications, especially for machine learning first steps. Also, associated standard errors are robust to misspecification when there is the same number of moment functions as parameters of interest.

We use these orthogonal moments and cross-fitting to construct debiased machine learning estimators of functions of high dimensional conditional quantiles and of dynamic discrete choice parameters with high dimensional state variables. We show that additional first steps needed for the orthogonal moment functions have no effect, globally, on average orthogonal moment functions. We give a general approach to estimating those additional first steps. We characterize double robustness and give a variety of new doubly robust moment functions. We give general and simple regularity conditions for asymptotic theory.

**KEYWORDS:** Local robustness, orthogonal moments, double robustness, semiparametric estimation, bias, GMM.

## 1. INTRODUCTION

MANY ECONOMIC AND CAUSAL PARAMETERS DEPEND on nonparametric or high dimensional first steps, denoted as  $\gamma$ , such as conditional expectations. Examples include dynamic discrete choice, games, average exact consumer surplus, and treatment effects. This

Zhao, and participants in seminars at Cambridge, Chicago, Columbia, Cornell, Harvard-MIT, Penn State, UCL, USC, UCSD, Yale, and Xiamen. B. Deaner provided superb research assistance.

paper shows how to construct moment functions for GMM estimators that are locally robust, referred to henceforth as orthogonal. Orthogonal moment functions are those where  $\gamma$  has no local effect on average moment functions, that is, the average moment functions are insensitive to small perturbations in  $\gamma$  around the probability limit (plim)  $\gamma_0$  of an estimator  $\hat{\gamma}$ . We show that such moment functions can be constructed by adding to identifying moment functions the first step influence function (FSIF) that gives the effect of  $\gamma$  on average identifying moment functions under general misspecification. Such orthogonal moments reduce bias from estimation of  $\gamma$  and lead to standard errors for parameters of interest that are robust to misspecification when there is the same number of moment functions as parameters. In constructing sample moments, we also cross-fit, a form of sample splitting where the moment function for each observation is evaluated at  $\hat{\gamma}$  that only use other observations, which further reduces bias. A GMM estimator based on orthogonal moment functions with cross-fitting is referred to here as debiased GMM.

Debiased GMM has several advantages over plug-in GMM where only the identifying moment functions are used. First, standard confidence intervals for debiased GMM are valid under local alternatives when  $\hat{\gamma}$  uses model selection, as in Chernozhukov, Hansen, and Spindler (2015), but for plug-in GMM are typically biased and invalid, similar to Leeb and Pötscher (2005). Second, for a regularized first step  $\hat{\gamma}$ , debiased GMM is typically much less biased than plug-in GMM. Thus, debiased GMM is preferred over plug-in GMM in the many applications where  $\hat{\gamma}$  involves model selection and/or regularization. Third, orthogonal moment functions will be doubly robust when they are linear or affine in  $\gamma$ , meaning that average moments do not depend on  $\gamma$  in those cases. We give this double robustness characterization and use it to derive new classes of doubly robust moment functions. Fourth, in important settings, debiased GMM has faster remainder rates than plug-in GMM, for example, Newey and Robins (2017). In addition, regularity conditions for debiased GMM are general and simple relative to those for plug-in GMM. We show asymptotic normality for debiased GMM for any  $\hat{\gamma}$  where certain mean-square consistency conditions hold and either one (under double robustness) or two (more generally) mean-square rates hold and that these conditions are generally not sufficient for plug-in GMM. Debiased GMM is computationally more complicated than plug-in GMM in requiring estimation of a first step  $\alpha$  in addition to  $\gamma$ , although estimation of  $\alpha$  is required anyway for standard errors for plug-in GMM, as in Newey (1994a).

Machine learning is useful for estimating economic and causal models where there are high dimensional covariates or state variables, for example, as in Belloni, Chen, Chernozhukov, and Hansen (2012), Robins et al. (2013), Belloni, Chernozhukov, and Hansen (2014), Farrell (2015), Belloni, Chernozhukov, Fernandez-Val, and Hansen (2017), and Athey, Imbens, and Wager (2018). Machine learning methods that are useful for these purposes include Lasso, Dantzig, boosting, neural nets, random forests, and others. Orthogonal moment functions reduce model selection and/or regularization biases which are common for machine learning first steps. Cross-fitting for debiased GMM also reduces bias and avoids the need for Donsker conditions, which are not known to hold for many machine learning first steps. The large sample theory given here imposes only mean-square convergence properties which will hold for a variety of machine learning first steps. The advantages of debiased GMM make it preferred to plug-in GMM for many machine learning first steps.

The orthogonal moment functions we give open the way to debiased GMM estimation of many objects of interest. We illustrate by constructing debiased GMM estimators for functionals of quantile regressions and for parameters of dynamic discrete choice models. The quantile regression estimator allows for high dimensional regressors. The dynamic

discrete choice estimator is based on machine learners of conditional choice probabilities allowing for high dimensional state variables. The estimator incorporates a novel Lasso estimator where the left-hand-side variable is a function of a machine learner. The estimator and the results we give provide a prototype for using machine learning for dynamic structural models. The relationship of the orthogonal moments in this paper to previous literature is discussed in Section 4.

Debiased GMM is more robust to the additional first step  $\alpha$  than previously recognized in the literature. We show that the average of orthogonal moment functions does not depend on  $\alpha$  when  $\gamma$  is equal to the plim  $\gamma_0$  of  $\hat{\gamma}$ . Consequently, estimators of  $\alpha$  are not required to converge faster than  $n^{-1/4}$ , where  $n$  is the sample size. We also give automatic estimators of  $\alpha$  that use orthogonality in their construction and generalize Chernozhukov, Newey, and Robins (2018) and Chernozhukov, Newey, and Singh (2018) to general moment functions and a larger set of first steps.

Doubly robust moment functions have been constructed by Robins, Rotnitzky, and Zhao (1994), Robins and Rotnitzky (2001), Graham (2011), and Firpo and Rothe (2019). This paper innovates by characterizing double robustness and deriving large classes of new doubly robust moment functions, including affine functionals of least squares regressions and other first steps obtained from orthogonality of residuals and instrumental variables.

Targeted maximum likelihood (van der Laan and Rubin (2006)) based on machine learners has been considered by van der Laan and Rose (2011). Here we focus on debiased GMM.

Recent work on debiased machine learning by Chernozhukov et al. (2018), Chernozhukov, Newey, and Robins (2018), and Chernozhukov, Newey, and Singh (2018) is partly based on and is also generalized by this paper. The construction of orthogonal moments given here was described in Chernozhukov et al. (2018), which cited this paper for that construction and contains no results from this paper. The asymptotic theory in this paper uses the orthogonal moment construction here to improve on the asymptotic theory of Chernozhukov et al. (2018), as described in Section 6. The doubly robust moment conditions considered in Chernozhukov, Newey, and Robins (2018) and Chernozhukov, Newey, and Singh (2018) were derived in the first version of this paper, Chernozhukov, Escanciano, Ichimura, and Newey (2016), and the asymptotic theory in those other papers uses theory given in this paper. The automatic machine learner given here for the additional unknown functions  $\alpha$  generalizes that in Chernozhukov, Newey, and Singh (2018). In addition, Newey and Robins (2017) and Hirshberg and Wager (2019) were concerned with linear functions of a regression that are formulated here. Furthermore, Bonhomme and Weidner (2018) have shown the importance of orthogonal moment functions in specification analysis, Foster and Syrgkanis (2019) in deriving rates of convergence for machine learners, Semenova (2018) for machine learning for partially identified models, and Singh and Sun (2019) for machine learning of complier effects.

There are other biases arising from nonlinearity of moment conditions in the first step  $\hat{\gamma}$ . Cattaneo and Jansson (2018) and Cattaneo, Jansson, and Ma (2018) gave useful bootstrap and jackknife methods that reduce nonlinearity bias. Newey and Robins (2017) showed that one can also remove this bias by cross-fitting in some settings. We use cross-fitting in this paper.

Section 2 describes orthogonal moment functions and debiased GMM. Section 3 gives the quantile and dynamic discrete choice examples. Section 4 shows and discusses orthogonality. Section 5 gives novel classes of doubly robust moment functions and characterizes double robustness. Section 6 provides general and simple asymptotic theory for debiased GMM. Proofs and precise bias results for plug-in estimators are given in the appendixes.

## 2. DEBIASED GMM

This section describes the orthogonal moment functions, cross-fitting, and automatic estimators of  $\alpha$  we use for debiased GMM. We begin with an example.

EXAMPLE 1: An illustrative example has data observation  $W = (Y, X, Z)$  and parameter of interest  $\theta_0 = E[Z\gamma_0(X)] = E[\alpha_0(X)\gamma_0(X)]$  for  $\gamma_0(X) = E[Y|X]$  and  $\alpha_0(X) = E[Z|X]$ . This example is of interest in its own right as the component of the expected conditional covariance  $E[\text{Cov}(Z, Y|X)] = E[Z\gamma_0(X)] - \theta_0$  that depends on unknown functions. This covariance is useful for the analysis of covariance and for estimation of a partially linear model (Robinson (1988)). We specify the identifying moment function as  $z\gamma(x) - \theta$  and the plim of  $\hat{\gamma}$  to be  $E[Y|X]$ , so that  $\hat{\gamma}$  is a nonparametric regression estimator. Model selection and/or regularization of  $\hat{\gamma}$  will typically lead to large biases in a plug-in estimator  $\hat{\theta} = \sum_{i=1}^n Z_i \hat{\gamma}(X_i)/n$  as previously mentioned, for  $n$  data observations  $W_i$ . An orthogonal moment function can be constructed by adding the FSIF, which for the identifying moment function  $z\gamma(x) - \theta$  was shown to be  $\alpha(x)[y - \gamma(x)]$  in Proposition 4 of Newey (1994a). The orthogonal moment function is the sum of the identifying moment function and the FSIF, given by

$$\psi(w, \gamma, \alpha, \theta) := z\gamma(x) - \theta + \alpha(x)[y - \gamma(x)].$$

In this example, it follows by iterated expectations and subtracting and adding  $\theta_0$  that

$$\begin{aligned} E[\psi(W, \gamma, \alpha, \theta)] &= E[\alpha_0(X)\gamma(X)] - \theta + E[\alpha(X)\{\gamma_0(X) - \gamma(X)\}] \\ &= \theta_0 - \theta - E[\{\alpha(X) - \alpha_0(X)\}\{\gamma(X) - \gamma_0(X)\}]. \end{aligned} \quad (2.1)$$

Here departures of  $(\gamma, \alpha)$  from  $(\gamma_0, \alpha_0)$  have only a second-order effect on the average orthogonal moment function, leading to small bias from first step estimation.

## 2.1. Constructing Orthogonal Moment Functions

To describe debiased GMM in general, let  $\theta$  denote a finite dimensional parameter vector of interest,  $\gamma$  be the unknown first step function from the Introduction, and  $W$  a data observation with unknown cumulative distribution function (CDF)  $F_0$ . We assume that there is a vector  $g(w, \gamma, \theta)$  of known functions of a possible realization  $w$  of  $W$ ,  $\gamma$ , and  $\theta$  such that

$$E[g(W, \gamma_0, \theta_0)] = 0,$$

where  $E[\cdot]$  is the expectation under  $F_0$  and  $\gamma_0$  is the probability limit (plim) under  $F_0$  of a first step estimator  $\hat{\gamma}$ . Here we assume that  $\theta_0$  is identified by these moments, that is, that  $\theta_0$  is the unique solution to  $E[g(W, \gamma_0, \theta)] = 0$  over  $\theta$  in some set  $\Theta$ .

The identifying moment functions  $g(w, \gamma, \theta)$  and  $\hat{\gamma}$  can be used to estimate the parameter of interest  $\theta_0$ . Let  $W_1, \dots, W_n$  be a sample of i.i.d. data observations. Estimated sample moment functions can be formed by plugging the first step estimator  $\hat{\gamma}$  into  $g(W_i, \gamma, \theta)$  and averaging over data observations to obtain  $\sum_{i=1}^n g(W_i, \hat{\gamma}, \theta)/n$ . One could form a “plug-in” GMM estimator by minimizing a quadratic form in these estimated sample moments, but such an estimator will be highly biased by first step model selection and/or regularization as discussed in the Introduction. This bias can be reduced by using orthogonal moment functions.

The orthogonal moment functions we give are based on influence functions. To describe them, we need a few additional concepts and notation. Let  $F$  denote a possible CDF for a data observation  $W$  and suppose that the plim of  $\hat{\gamma}$  is  $\gamma(F)$  when  $F$  is the true distribution of a data observation  $W$ . Here  $\gamma(F)$  is the plim of  $\hat{\gamma}$  under general misspecification, similar to Newey (1994a), where  $F$  is unrestricted except for regularity conditions such as existence of  $\gamma(F)$  or the expectation of certain functions of the data. For example, if  $\hat{\gamma}(x)$  is a nonparametric estimator of  $E[Y|X = x]$ , then  $\gamma(F)(x) = E_F[Y|X = x]$  is the conditional expectation function when  $F$  is the true distribution of  $W$ , which is well defined under the regularity condition that  $E_F[|Y|]$  is finite. We assume that  $\gamma(F_0) = \gamma_0$ , consistent with  $\gamma_0$  being the plim of  $\hat{\gamma}$  when  $F_0$  is the CDF of  $W$ .

Next, let  $F_0$  again denote the true distribution of  $W$ ,  $H$  be some alternative distribution that is unrestricted except for regularity conditions, and  $F_\tau = (1 - \tau)F_0 + \tau H$  for  $\tau \in [0, 1]$ . We assume that  $H$  is chosen so that  $\gamma(F_\tau)$  exists for  $\tau$  small enough and possibly other regularity conditions are satisfied. We make the key assumption that there exists a function  $\phi(w, \gamma, \alpha, \theta)$  such that

$$\begin{aligned} \frac{d}{d\tau} E[g(W, \gamma(F_\tau), \theta)] &= \int \phi(w, \gamma_0, \alpha_0, \theta) H(dw), \\ E[\phi(W, \gamma_0, \alpha_0, \theta)] &= 0, \quad E[\phi(W, \gamma_0, \alpha_0, \theta)^2] < \infty, \end{aligned} \quad (2.2)$$

for all  $H$  and all  $\theta$ . Here  $\alpha$  is an unknown function, additional to  $\gamma$ , on which only  $\phi(w, \gamma, \alpha, \theta)$  depends,  $\alpha_0$  is the  $\alpha$  such that equation (2.2) is satisfied, and  $d/d\tau$  is the derivative from the right (i.e., for nonnegative values of  $\tau$ ) at  $\tau = 0$ . This equation is a well-known Gateaux derivative characterization of the influence function  $\phi(w, \gamma_0, \alpha_0, \theta)$  of the functional  $\mu(F) = E[g(W, \gamma(F), \theta)]$ , as in Von Mises (1947), Hampel (1974), and Huber (1981). The restriction that  $\gamma(F_\tau)$  exists allows  $\phi(w, \gamma_0, \alpha_0, \theta)$  to be the influence function when  $\gamma(F)$  is only well defined for certain types of distributions, such as when  $\gamma(F)$  is a conditional expectation or pdf. Also,  $\phi(w, \gamma_0, \alpha_0, \theta)$  is unique because we are not restricting  $H$  except for regularity conditions. Here  $\gamma_0$  and  $\alpha_0$  can depend on  $\theta$ , equation (2.2) is assumed to hold for each  $\theta \in \Theta$ , and  $F_0$  and  $H$  do not depend on  $\theta$ .

We refer to  $\phi(w, \gamma, \alpha, \theta)$  as the *first step influence function* (FSIF) because it characterizes the local effect of the first step plim  $\gamma(F)$  on the average moment function  $\mu(F)$  as  $F_\tau$  varies away from  $F_0$  in any direction  $H$ . The FSIF can be calculated from the derivative in equation (2.2) by evaluating it where  $H$  is a point mass, for example, as shown in Ichimura and Newey (2021), or as a solution to equation (3.9) of Newey (1994a). Equation (2.1) (and equation (3.9) of Newey (1994a)) is a strong condition with existence of  $\phi(w, \gamma, \alpha, \theta)$  generally equivalent to  $E[g(W, \gamma(F), \theta)]$  having a finite semiparametric variance bound. This  $\phi(w, \gamma, \alpha, \theta)$  coincides with the “adjustment term” of Newey (1994a) that accounts for the nonparametric estimator  $\hat{\gamma}$  in the asymptotic variance of plug-in GMM when model selection and regularization biases are small. Equation (2.2) is essentially equivalent to equation (3.9) of Newey (1994a), with the requirement that equation (2.2) be satisfied for all  $H$  in a regular, rich enough class replacing the requirement that equation (3.9) of Newey (1994a) be satisfied for all regular parametric submodels, as further explained in Ichimura and Newey (2021).

Orthogonal moment functions can be constructed by adding the FSIF to the identifying moment functions to obtain

$$\psi(W, \gamma, \alpha, \theta) = g(W, \gamma, \theta) + \phi(W, \gamma, \alpha, \theta). \quad (2.3)$$

This vector of moment functions has two key orthogonality properties. The first property is that, for the set  $\Gamma$  of possible directions of departure of  $\gamma(F)$  from  $\gamma_0$ , which we assume to be linear,

$$\frac{d}{dt}E[\psi(W, \gamma_0 + t\delta, \alpha_0, \theta)] = 0 \quad \text{for all } \delta \in \Gamma \text{ and } \theta \in \Theta, \quad (2.4)$$

where  $t$  is a scalar and the derivative is evaluated at  $t = 0$ . Here  $\delta$  represents a possible direction of deviation of  $\gamma(F)$  from  $\gamma_0$  and  $t$  the size of a deviation. This property means that varying  $\gamma$  away from  $\gamma_0$  has no effect, locally, on  $E[\psi(W, \gamma, \alpha_0, \theta)]$ . The second property is that for the set  $\mathcal{A}$  of  $\alpha_0$  such that equation (2.2) is satisfied for some  $F_0$ ,

$$E[\phi(W, \gamma_0, \alpha, \theta)] = 0 \quad \text{for all } \theta \in \Theta \text{ and } \alpha \in \mathcal{A}. \quad (2.5)$$

Consequently, varying  $\alpha$  will have no effect, globally, on  $E[\psi(W, \gamma_0, \alpha, \theta)] = E[g(W, \gamma_0, \theta)] + E[\phi(W, \gamma_0, \alpha, \theta)] = E[g(W, \gamma_0, \theta)]$ . These properties are shown in Section 4.

EXAMPLE 1—continued: Equation (2.1) gives  $E[\psi(W, \gamma_0 + t\delta, \alpha_0, \theta)] = \theta_0 - \theta$  and iterated expectations gives  $E[\phi(W, \gamma_0, \alpha, \theta)] = E[\alpha(X)\{Y - \gamma_0(X)\}] = 0$ , so that both of equations (2.4) and (2.5) are satisfied.

Constructing orthogonal moment functions is greatly facilitated by the wide variety of known  $\phi(W, \gamma, \alpha, \theta)$ . For first step least squares projections (including conditional expectations), density weighted conditional means, and their derivatives  $\phi(W, \gamma, \alpha, \theta)$  are given in Newey (1994a). Hahn (1998) and Hirano, Imbens, and Ridder (2003) used those results to obtain  $\phi(W, \gamma, \alpha, \theta)$  for treatment effect estimators. Bajari, Hong, Krainer, and Nekipelov (2010) derived  $\phi(W, \gamma, \alpha, \theta)$  for some first steps used in structural estimation. Hahn and Ridder (2013, 2019) derived  $\phi(W, \gamma, \alpha, \theta)$  for generated regressors that depend on first step conditional expectations. Chen and Liao (2015) derived  $\phi(W, \gamma, \alpha, \theta)$  for a first step that approximately minimizes the sample average of a function of a data observation and  $\gamma$ . Ai and Chen (2007, p. 40) and Ichimura and Newey (2021) gave  $\phi(W, \gamma, \alpha, \theta)$  for first step estimators of functions satisfying conditional moment and orthogonality conditions, respectively. Semenova (2018) derived  $\phi(W, \gamma, \alpha, \theta)$  for support functions used in partial identification. This wide variety of known  $\phi(W, \gamma, \alpha, \theta)$  can be used to construct orthogonal moment functions in many settings.

## 2.2. Cross-Fitting

We combine orthogonal moment functions with cross-fitting, a form of sample splitting, to construct debiased sample moments; for example, see Bickel (1982), Schick (1986), Klaassen (1987), and Chernozhukov et al. (2018). Partition the observation indices ( $i = 1, \dots, n$ ) into  $L$  groups  $I_\ell$  ( $\ell = 1, \dots, L$ ). Consider  $\hat{\gamma}_\ell$ ,  $\hat{\alpha}_\ell$ , and an initial estimator  $\tilde{\theta}_\ell$  that are constructed using all observations *not* in  $I_\ell$ . Debiased sample moment functions are

$$\begin{aligned} \hat{\psi}(\theta) &= \hat{g}(\theta) + \hat{\phi}, & \hat{g}(\theta) &= \frac{1}{n} \sum_{\ell=1}^L \sum_{i \in I_\ell} g(W_i, \hat{\gamma}_\ell, \theta), \\ \hat{\phi} &= \frac{1}{n} \sum_{\ell=1}^L \sum_{i \in I_\ell} \phi(W_i, \hat{\gamma}_\ell, \hat{\alpha}_\ell, \tilde{\theta}_\ell). \end{aligned} \quad (2.6)$$

Large sample properties are given in Section 6 for fixed  $L$ . The choice of  $L = 5$  works well based on a variety of empirical examples and in simulations, for medium sized data sets of a few thousand observations; see Chernozhukov et al. (2018). The choice  $L = 10$  works well for small data sets with the larger  $L$  providing more observations for construction of  $\hat{\gamma}_\ell$  and  $\hat{\alpha}_\ell$ .

The cross-fitting used here, where  $\hat{\psi}(\theta)$  is an average over observations not used to form  $\hat{\gamma}_\ell$  and  $\hat{\alpha}_\ell$ , eliminates bias due to averaging over observations that are used to construct the first step. Eliminating such “own observation” bias helps remainders converge faster to zero, for example, as in Newey and Robins (2017), and can be important in practice, for example, as in the jackknife instrumental variables estimators of Angrist and Krueger (1995) and Blomquist and Dahlberg (1999). It also eliminates the need for Donsker conditions for  $\hat{\gamma}_\ell$  and  $\hat{\alpha}_\ell$ , which is important for many machine learning first steps that are not known to satisfy such conditions, as discussed in Chernozhukov et al. (2018).

A debiased GMM estimator is

$$\hat{\theta} = \arg \min_{\theta \in \Theta} \hat{\psi}(\theta)' \hat{Y} \hat{\psi}(\theta), \quad (2.7)$$

where  $\hat{Y}$  is a positive semi-definite weighting matrix and  $\Theta$  is the set of parameter values. A choice of  $\hat{Y}$  that minimizes the asymptotic variance of  $\hat{\theta}$  will be  $\hat{Y} = \hat{\Psi}^{-1}$ , for

$$\hat{\Psi} = \frac{1}{n} \sum_{\ell=1}^L \sum_{i \in I_\ell} \hat{\psi}_{i\ell} \hat{\psi}_{i\ell}', \quad \hat{\psi}_{i\ell} = g(W_i, \hat{\gamma}_\ell, \tilde{\theta}_\ell) + \phi(W_i, \hat{\gamma}_\ell, \hat{\alpha}_\ell, \tilde{\theta}_\ell).$$

There is no need to account for the presence of  $\hat{\gamma}_\ell$  and  $\hat{\alpha}_\ell$  in  $\hat{\psi}_{i\ell}$  because of the orthogonality of  $\psi(w, \gamma, \alpha, \theta)$ . An estimator  $\hat{V}$  of the asymptotic variance of  $\sqrt{n}(\hat{\theta} - \theta_0)$  is

$$\hat{V} = (\hat{G}' \hat{Y} \hat{G})^{-1} \hat{G}' \hat{Y} \hat{\Psi} \hat{Y} \hat{G} (\hat{G}' \hat{Y} \hat{G})^{-1}, \quad \hat{G} = \frac{\partial \hat{g}(\hat{\theta})}{\partial \theta}. \quad (2.8)$$

The initial estimator  $\tilde{\theta}_\ell$  can be based on only the identifying moment conditions and constructed as

$$\tilde{\theta}_\ell = \arg \min_{\theta \in \Theta} \hat{g}_\ell(\theta)' \hat{Y}_\ell \hat{g}_\ell(\theta), \quad \hat{g}_\ell(\theta) = \frac{1}{n - n_\ell} \sum_{\ell' \neq \ell} \sum_{i \in I_{\ell'}} g(W_i, \tilde{\gamma}_{\ell\ell'}, \theta),$$

where  $\hat{Y}_\ell$  uses only observations not in  $I_\ell$ ,  $n_\ell$  is the number of observations in  $I_\ell$ , and  $\tilde{\gamma}_{\ell\ell'}$  uses observations not in  $I_\ell$  and not in  $I_{\ell'}$ . One could iterate on the initial estimator  $\tilde{\theta}_\ell$  in the debiased moments  $\hat{\psi}(\theta)$  and/or  $\hat{\Psi}$  by calculating  $\hat{\theta}$  and/or  $\hat{\Psi}$  a second time with  $\tilde{\theta}_\ell$  being a debiased GMM estimator obtained from a prior iteration. Because of the orthogonality condition (2.5), the use of  $\tilde{\theta}_\ell$  in constructing  $\hat{\psi}$  will not affect the asymptotic distribution of  $\hat{\theta}$ .

EXAMPLE 1—continued: Here  $\psi(w, \gamma, \theta) = z\gamma(x) - \theta + \alpha(x)[y - \gamma(x)]$ . Forming  $\hat{\psi}(\theta)$  as we have described and solving  $\hat{\psi}(\hat{\theta}) = 0$  for  $\hat{\theta}$  gives the debiased GMM estimator

$$\hat{\theta} = \frac{1}{n} \sum_{\ell=1}^L \sum_{i \in I_\ell} \{Z_i \hat{\gamma}_\ell(X_i) + \hat{\alpha}_\ell(X_i)[Y_i - \hat{\gamma}_\ell(X_i)]\}.$$

The efficiency of debiased GMM is entirely determined by the choice of moment functions, first step, and weighting matrix. The matrix  $\hat{\Psi}^{-1}$  is an optimal choice of weighting matrix as usual for GMM. The presence of  $\hat{\phi}$  in the orthogonal moment functions  $\hat{\psi}(\theta)$  does not affect identification of  $\theta$ . The FSIF has mean zero for all possible distributions of  $W$  so that  $\hat{\phi}$  will converge in probability to zero. The sole purpose of including  $\hat{\phi}$  is to remove the local effect of  $\hat{\gamma}_\ell$  on average moment functions.

### 2.3. Automatic Estimation of $\alpha_0$

The debiased moments require a first step estimator  $\hat{\alpha}_\ell$  with plim  $\alpha_0$ . When the form of  $\alpha_0$  is known, one can plug in nonparametric estimators of unknown components of  $\alpha_0$  to form  $\hat{\alpha}_\ell$ . We can also use the orthogonality of  $\psi(w, \gamma, \alpha_0, \theta)$  with respect to  $\gamma$  in equation (2.4) to construct estimators of  $\alpha_0$  without knowing the form of  $\alpha_0$ . This approach is “automatic” in only requiring the orthogonal moment function  $\psi(W, \gamma, \alpha, \theta)$  and data for construction of  $\hat{\alpha}_\ell$ .

Equation (2.4) can be thought of as a population moment condition for  $\alpha_0$  for each  $\delta$ . We can form a corresponding sample moment function by replacing the expectation by a sample average and  $\gamma_0$  and  $\theta_0$  by cross-fit estimators to obtain

$$\hat{\psi}_\gamma(\delta, \alpha) = \frac{d}{dt} \frac{1}{n - n_\ell} \sum_{\ell' \neq \ell} \sum_{i \in I_{\ell'}} \psi(W_i, \tilde{\gamma}_{\ell\ell'} + t\delta, \alpha, \tilde{\theta}_{\ell\ell'})|_{t=0}, \quad \delta \in \Gamma, \quad (2.9)$$

where  $\tilde{\gamma}_{\ell\ell'}$  and  $\tilde{\theta}_{\ell\ell'}$  do not depend on observations in  $I_\ell$  or  $I_{\ell'}$  and we assume that  $\psi(W_i, \tilde{\gamma}_{\ell\ell'} + t\delta, \alpha, \tilde{\theta}_{\ell\ell'})$  is differentiable in  $t$ . We can then replace  $\alpha$  by a sieve (i.e., parametric approximation) and estimate the sieve parameters using these sample moments for a variety of choices of  $\delta$ . We can also regularize to allow for a high dimensional specification for  $\alpha$ . The sample moments in equation (2.9) depend only on observations not in  $I_\ell$  so that the resulting  $\hat{\alpha}_\ell$  will also, as required for the cross-fitting in debiased GMM.

EXAMPLE 1—continued: Here  $\alpha_0$  is a function of  $X$  that has finite second moment and

$$\begin{aligned} \hat{\psi}_\gamma(\delta, \alpha) &= \frac{d}{dt} \frac{1}{n - n_\ell} \sum_{\ell' \neq \ell} \sum_{i \in I_{\ell'}} \{Z_i [\hat{\gamma}_{\ell\ell'}(X_i) + t\delta(X_i)] \\ &\quad + \alpha(X_i) [Y_i - \hat{\gamma}_{\ell\ell'}(X_i) - t\delta(X_i)] - \tilde{\theta}_{\ell\ell'}\} |_{t=0} \\ &= \frac{1}{n - n_\ell} \sum_{i \notin I_\ell} [Z_i - \alpha(X_i)] \delta(X_i). \end{aligned}$$

This is a sample moment corresponding to the population moment condition  $E[\{Z - \alpha_0(X)\}\delta(X)] = 0$ , which holds by  $\alpha_0(X) = E[Z|X]$ . If  $\alpha(X)$  was replaced by a linear combination  $\rho'b(x)$  of a dictionary  $b(x) = (b_1(x), \dots, b_p(x))'$  of functions and  $\delta(X)$  chosen to be one element  $b_j(X)$  of the dictionary, then the sample moment function is

$$\hat{\psi}_\gamma(b_j, \rho'b) = \frac{1}{n - n_\ell} \sum_{i \notin I_\ell} [Z_i - \rho'b(X_i)] b_j(X_i).$$

The collection of sample moment conditions  $\hat{\psi}_\gamma(b_j, \rho'b) = 0$  ( $j = 1, \dots, p$ ) are first-order conditions for minimizing the least squares objective function for the regression of  $Z_i$  on

$b(X_i)$ . Adding an  $L1$  penalty to this objective function and minimizing leads to the Lasso least squares estimator

$$\hat{\alpha}_\ell(x) = \hat{\rho}'b(x), \quad \hat{\rho} = \arg \min_{\rho} \sum_{i \notin I_\ell} [Z_i - \rho'b(X_i)]^2 / n + 2r \sum_{j=1}^p |\rho_j|.$$

The construction of  $\hat{\alpha}_\ell$  in Example 1 can be generalized to a wide class of regression settings that will be useful for many additional examples. This generalization builds on Example 1 to estimate more complicated objects, such as a functional of quantile regression in Example 2 below. We generalize  $\gamma$  from being a possible conditional expectation to being an element of a linear set  $\Gamma$ . In Example 1, where the conditional expectation is an unknown function of  $X$ , the  $\Gamma$  is all functions of  $X$  with finite second moment. Instead,  $\Gamma$  could, for example, be restricted to be linear combinations of a sequence  $(b_1(X), b_2(X), \dots)$ , corresponding to a high dimensional regression. A corresponding generalization of  $\gamma(F)$  being a conditional expectation is to  $\gamma(F)$  satisfying an orthogonality condition. For a scalar residual  $\lambda(w, \gamma(x))$ , we consider  $\gamma(F) \in \Gamma$  satisfying

$$E_F[\delta(X)\lambda(W, \gamma(F)(X))] = 0 \quad \text{for all } \delta \in \Gamma. \quad (2.10)$$

The  $\gamma(F)(X) = E_F[Y|X]$  of Example 1 satisfies this equation for  $\lambda(w, \gamma(x)) = y - \gamma(x)$  and  $\Gamma$  equal to all functions of  $X$  with finite second moment. A high dimensional quantile regression in Example 2 will satisfy this equation for  $\lambda(w, \gamma(x)) = \zeta - 1(y < \gamma(x))$  for  $0 < \zeta < 1$  and  $\Gamma$  equal to linear combinations of  $(b_1(X), b_2(X), \dots)$ . The FSIF for  $\gamma(F)$  in equation (2.10) is

$$\phi(w, \gamma, \alpha, \theta) = \alpha(x, \theta)\lambda(w, \gamma(x)),$$

as in Ai and Chen (2007, p. 40) for conditional moments when  $\Gamma$  is unrestricted, and Ichimura and Newey (2021) in general, where the formula for  $\alpha(x, \theta)$  is given.

Example 1 can be further generalized to consider a general vector of identifying moment functions other than  $z\gamma(x) - \theta$ . Here there will be one  $\alpha(x, \theta)$  for each component of  $g(w, \gamma, \theta)$ . Let  $(b_1(X), b_2(X), \dots)$  “span”  $\Gamma$ , meaning any  $\delta \in \Gamma$  can be well approximated in mean-square by a finite linear combination of  $b_j(X)$ . We will describe an estimator for the  $k$ th component  $\alpha_k(x, \theta)$  of  $\alpha(x, \theta)$  corresponding to the  $k$ th component  $g_k(w, \gamma, \theta)$  of  $g(w, \gamma, \theta)$ . Let  $\hat{\lambda}_{i\gamma} = -d\lambda(W_i, \hat{\gamma}_{\ell\ell'}(X_i) + t)/dt|_{t=0}$  for  $i \in I_{\ell'}$  and let  $e_j$  denote the  $j$ th column of a  $p$ -dimensional identity matrix. Then for  $b(X) = (b_1(X), \dots, b_p(X))'$ ,

$$\begin{aligned} \hat{\psi}_{k\gamma}(b_j, \rho'b) &= \hat{M}_{jk\ell} - e_j'\hat{Q}_\ell\rho, \\ \hat{M}_{jk\ell} &= \frac{1}{n - n_\ell} \sum_{\ell' \neq \ell} \sum_{i \in I_{\ell'}} \frac{d}{dt} g_k(W_i, \hat{\gamma}_{\ell\ell'} + tb_j, \tilde{\theta}_{\ell\ell'}), \\ \hat{Q}_\ell &= \frac{1}{n - n_\ell} \sum_{\ell' \neq \ell} \sum_{i \in I_{\ell'}} \hat{\lambda}_{\gamma i} b(X_i) b(X_i)', \end{aligned}$$

corresponding to the  $k$ th orthogonal moment function  $\psi_k(w, \gamma, \alpha) = g_k(w, \gamma, \theta) + \alpha_k(x, \theta)\lambda(w, \gamma(x))$  and the  $j$ th component  $b_j$  of  $b(X)$ . Let  $\hat{M}_{k\ell} = (\hat{M}_{1k\ell}, \dots, \hat{M}_{pk\ell})'$  so that

$$\hat{\psi}_{k\gamma}(b_j, \rho'b) = \frac{\partial}{\partial \rho_j} \{ \hat{M}_{k\ell}'\rho - \rho'\hat{Q}_\ell\rho/2 \}.$$

The collection of sample moment conditions  $-2\hat{\psi}_{k\gamma}(b_j, \rho'b) = 0$  ( $j = 1, \dots, p$ ) are first-order conditions for minimizing  $-2\hat{M}'_{k\ell}\rho + \rho'\hat{Q}_\ell\rho$ . Here we assume that we can normalize so that  $v_\rho(X) := -dE[\lambda(W, \gamma_0(X) + t)|X]/dt|_{t=0} > 0$  and hence  $\hat{Q}_\ell$  is positive semi-definite asymptotically. Adding an  $L1$  penalty to this objective function and minimizing leads to the Lasso minimum distance estimator

$$\hat{\alpha}_{k\ell}(x) = \hat{\rho}'_{k\ell}b(x), \quad \hat{\rho}_{k\ell} = \arg \min_{\rho} \left\{ -2\hat{M}'_{k\ell}\rho + \rho'\hat{Q}_\ell\rho + 2r \sum_{j=1}^p |\rho_j| \right\}. \quad (2.11)$$

As usual for Lasso, we assume that each element  $b_j(x)$  of the dictionary has been standardized to have standard deviation 1. One choice of  $r$  would be  $\hat{r} = \arg \min_r \sum_{\ell=1}^L \{-2\hat{M}'_{k\ell}\hat{\rho}^r_{k\ell} + \hat{\rho}^r_{k\ell}'\hat{Q}_\ell\hat{\rho}^r_{k\ell}\}$  that minimizes a cross-validation criterion where  $\hat{\rho}^r_{k\ell}$  is from equation (2.11) for a given  $r$  and the minimization is over a grid of  $r$  values.

This estimator  $\hat{\alpha}_{k\ell}(x)$  of  $\alpha_{k0}(x, \theta_0)$  generalizes that of Chernozhukov, Newey, and Singh (2018) to allow for a residual  $\lambda(w, \gamma(x))$  other than  $y - \gamma(x)$  and a general moment function. The nested sample splitting used for  $\hat{\gamma}_{\ell\ell'}(X_i)$  requires that the first step learner be computed for  $L^2$  subsamples. Use of  $\hat{\gamma}_\ell(x)$  as a starting value for computation of each  $\hat{\gamma}_{\ell\ell'}(X_i)$  may aid in this computation. The nested cross-fitting allows for a very general first step that need only have a mean-square convergence rate.

Orthogonality was used to estimate unknown components of doubly robust moment functions for the average treatment effect by Vermeulen and Vansteelandt (2015), Tan (2020), and Avagyan and Vansteelandt (2021) in order to obtain standard errors that are robust to misspecification. We use orthogonality here to estimate the unknown  $\alpha_0$  in the FSIF for a general identifying moment function and first step. The resulting standard errors are robust to misspecification because the FSIF takes full account of the plim of  $\hat{\gamma}$  under general misspecification.

It would be interesting to use the moment functions (2.9) to construct  $\hat{\alpha}$  for first steps other than the generalized linear regression  $\gamma(F)$  in equation (2.10). That is beyond the scope of this paper and is reserved to future work, including identification of  $\alpha_0$  and asymptotic theory for  $\hat{\alpha}$ .

This approach to estimating the FSIF uses its form  $\phi(w, \gamma, \alpha, \theta)$  to construct an estimator of  $\alpha_0$ . This approach is parsimonious in estimating only unknown parts of  $\phi(w, \gamma, \alpha, \theta)$  rather than the whole function. It is also possible to estimate the entire FSIF using just the first step and the identifying moments. Such estimators are available for first step series and kernel estimation. For first step series estimation, an estimator of  $\phi(w, \gamma, \alpha, \theta)$  can be constructed by treating the first step estimator as if it were parametric and applying a standard formula for parametric two-step estimators, for example, as in Newey (1994a), Akerberg, Chen, and Hahn (2012), and Chen and Liao (2015). For parametric maximum likelihood, the resulting orthogonal moment functions are the basis of Neyman's (1959) C-alpha test. For first step kernel estimation, one can use the numerical influence function estimator of Newey (1994b) to estimate  $\phi(w, \gamma, \alpha, \theta)$ , as suggested in a previous version of this paper and shown to work in a low dimensional nonparametric setting in Bravo, Escanciano, and van Keilegom (2020). The idea is to differentiate with respect to the effect of the  $i$ th observation on sample moments. Kernel estimators do not seem well suited to high dimensional settings so we do not consider them here.

It is also possible to estimate the FSIF using a numerical derivative version of equation (2.2). This approach has been given in Carone, Luedtke, and van der Laan (2019) and Bravo, Escanciano, and van Keilegom (2020) for construction of orthogonal moment

functions. We focus here on the more parsimonious approach of estimating  $\alpha_0$  when there is a known form  $\phi(w, \gamma, \alpha, \theta)$  for the FSIF.

### 3. FURTHER EXAMPLES OF DEBIASED GMM

In this section, we give two fully worked out examples of debiased GMM estimators, functionals of quantile regressions, and structural parameters of a dynamic discrete choice model.

#### 3.1. Example 2: Functional of a Quantile Regression

The object of interest in this example is an expected linear function of a quantile regression

$$\begin{aligned}\theta_0 &= E[m(W, \gamma_0)], & \gamma(F) &= \arg \min_{\gamma \in \Gamma} E_F[v(Y - \gamma(X))], \\ v(u) &= [\zeta - 1(u < 0)]u, & 0 < \zeta < 1,\end{aligned}\tag{3.1}$$

where  $m(w, \gamma)$  is a linear functional of  $\gamma$ ,  $Y$  is a dependent variable of interest,  $\Gamma$  is a linear set of functions of  $x$  (such as all functions of  $X$  with finite second moment), and we assume the minimum  $\gamma(F)$  exists. An example of  $m(w, \gamma)$  is a weighted average derivative of  $\gamma$  where  $m(w, \gamma) = \int \omega(x)[\partial \gamma(x)/\partial x_1] dx$  for a weight  $\omega(x)$ . Here the identifying moment function is  $g(w, \gamma, \theta) = m(w, \gamma) - \theta$ . The first-order condition for this  $\gamma(F)$  is equation (2.10) with  $\lambda(w, \gamma(x)) = \zeta - 1(y < \gamma(x))$ , so the FSIF has the form  $\phi(w, \gamma, \alpha) = \alpha(x)\lambda(y, \gamma(x))$ , as in Section 2.3.

In this example, the automatic estimator  $\hat{\alpha}_\ell$  of equation (2.11) does not exist because  $\lambda(w, \gamma(x) + t)$  is not continuous in  $\gamma$  and hence not differentiable. We address this complication by using kernel weighting in the construction of a  $\hat{Q}_\ell$  to use in equation (2.11). Let  $\hat{\gamma}_\ell(x)$  be a learner of  $\gamma_0$ , computed from observations not in  $I_\ell$ , and  $\hat{\gamma}_{\ell\ell'}(x)$  be computed from observations not in  $I_\ell$  or  $I_{\ell'}$ . Also let  $K(u)$  be a bounded, univariate kernel, with  $\int K(u) du = 1$  and  $\int K(u)u du = 0$ ,  $h$  a bandwidth, and  $b(x)$  be a  $p \times 1$  vector of functions of  $x$ . We specify that

$$\hat{Q}_\ell = \frac{1}{n - n_\ell} \sum_{\ell' \neq \ell} \sum_{i \in I_{\ell'}} \frac{1}{h} K\left(\frac{Y_i - \hat{\gamma}_{\ell\ell'}(X_i)}{h}\right) b(X_i) b(X_i)'.$$

The role of the kernel term in this  $\hat{Q}_\ell$  is to smooth over the discontinuity in  $\lambda(w, \gamma(x)) = \zeta - 1(y < \gamma(x))$  at  $\gamma(x) = y$ . This  $\hat{Q}_\ell$  estimates  $E[f(0|X)b(X)b(X)']$  where  $f(0|X)$  is the conditional pdf of  $Y - \gamma_0(X)$  evaluated 0.

A debiased GMM estimator of  $\theta_0$  can be formed from any learner  $\hat{\gamma}_\ell$  of  $\gamma_0$  as

$$\begin{aligned}\hat{\theta} &= \frac{1}{n} \sum_{\ell=1}^L \sum_{i \in I_\ell} [m(W_i, \hat{\gamma}_\ell) + \hat{\alpha}_\ell(X_i) \lambda(W_i, \hat{\gamma}_\ell(X_i))], & \hat{V} &= \frac{1}{n} \sum_{\ell=1}^L \sum_{i \in I_\ell} \hat{\psi}_{i\ell}^2, \\ \hat{\alpha}_\ell(x) &= b(x)' \hat{\rho}_\ell, & \hat{\rho}_\ell &= \arg \min_{\rho} \left\{ -2\hat{M}'_\ell \rho + \rho' \hat{Q}_\ell \rho + 2r \sum_{j=1}^p |\rho_j| \right\}, \\ \hat{M}_{\ell j} &= \frac{1}{n - n_\ell} \sum_{i \notin I_\ell} m(W_i, b_j), & \hat{M}_\ell &= (\hat{M}_{\ell 1}, \dots, \hat{M}_{\ell p})',\end{aligned}\tag{3.2}$$

where  $\hat{\psi}_{it} = m(W_i, \hat{\gamma}_\ell) + \hat{\alpha}_\ell(X_i)\lambda(W_i, \hat{\gamma}_\ell(X_i)) - \hat{\theta}$ . The asymptotic theory for this estimator is given in Section 6. That theory requires that the regularization constant  $r$  for  $\hat{\alpha}_\ell$  goes to zero slower than the conventional Lasso rate of  $\sqrt{\ln(p)/n}$ , in order to accommodate the presence of kernel weighting and  $\hat{\gamma}_{\ell\ell'}(X_i)$  in  $\hat{Q}_\ell$ .

Previously, Chaudhuri, Doksum, and Samarov (1997) gave a plug-in kernel estimator of the average derivative of a conditional quantile and the FSIF for that functional. Akerberg, Chen, Hahn, and Liao (2014) also gave an expression for the FSIF for functionals of conditional quantiles other than the weighted average derivative. Example 2 innovates in giving a debiased GMM estimator for a general linear functional of a quantile regression. Also, the  $\hat{\alpha}_\ell(x)$  here is a linear combination of a dictionary of functions rather than a ratio of a function of  $X$  and an estimator of the conditional pdf of  $Y - \gamma_0(X)$  as was used previously for estimating asymptotic variances.

### 3.2. Example 3: Dynamic Discrete Choice

For dynamic discrete choice with high dimensional state variables, we estimate structural parameters via learners of conditional choice probabilities. This approach replaces computation of expected value functions with nonparametric estimation as suggested in Hotz and Miller (1993). For simplicity, we focus this example on binary choice, providing methods and results that will be available for the more complicated models employed more widely in practice. In particular, we provide a Lasso estimator of conditional value function differences where the dependent variable is a function of estimated future choice probabilities. In Section 6, we provide convergence rate results for this estimator. We also give the FSIF for this kind of first step. This analysis provides a prototype for estimation of dynamic structural models with high dimensional state variables.

In dynamic binary choice, individuals choose between two alternatives  $j = 1$  and  $j = 2$  in  $T$  time periods to maximize the expected present discounted value of per period utility  $U_{jt} = D_j(X_t)' \theta_0 + \varepsilon_{jt}$  ( $j = 1, 2$ ;  $t = 1, \dots, T$ ), where  $\varepsilon_{jt}$  is i.i.d. with known CDF, independent of the entire history  $\{X_t\}_{t=1}^\infty$  of a state variable vector  $X_t$ , and  $X_t$  is Markov of order 1 and stationary. The parameter of interest is  $\theta_0$ . We develop an estimator that allows for high dimensional  $X_t$ .

We assume that choice 1 is a renewal choice where the conditional distribution of  $X_{t+1}$  given  $X_t$  and choice 1 does not depend on  $X_t$ . We also assume that  $D_1(X_t) = (-1, 0)'$  and the first element of  $D_2(X_t)$  equals 0 so that the first element in  $\theta$  is a binary choice constant. Let  $Y_{jt}$  equal a dummy variable equal to 1 when choice  $j$  is made and  $\gamma_{10}(X_t) = \Pr(Y_{2t} = 1|X_t)$  be the conditional choice probability of alternative 2. Also let  $V(X_t)$  denote the expected value function. As in Hotz and Miller (1993), there is a known function  $H(p)$  such that for  $\gamma_{20}(X_t) = E[H(\gamma_{10}(X_{t+1}))|X_t, Y_{2t} = 1]$  and  $\gamma_{30} = E[H(\gamma_{10}(X_{t+1}))|Y_{1t} = 1]$ ,

$$E[V(X_{t+1})|X_t, Y_{2t} = 1] - E[V(X_{t+1})|Y_{1t} = 1] = \gamma_{20}(X_t) - \gamma_{30}. \quad (3.3)$$

For example, when  $\varepsilon_{1t}$  and  $\varepsilon_{2t}$  are independent Type I extreme value, this equation is satisfied for  $H(p) = 0.5227 - \ln(1 - p)$ . Then for the CDF  $\Lambda(a)$  of  $\varepsilon_{t1} - \varepsilon_{t2}$ ,  $D(X_t) = D_2(X_t) - D_1(X_t)$ , and  $\delta$  the discount factor, the conditional choice probability for  $j = 2$  is

$$\begin{aligned} \Pr(Y_{2t} = 1|X_t) &= \Lambda(a(X_t, \theta_0, \gamma_{20}, \gamma_{30})), \\ a(x, \theta, \gamma_2, \gamma_3) &= D(x)' \theta + \delta \{\gamma_2(x) - \gamma_3\}. \end{aligned} \quad (3.4)$$

We consider data of i.i.d. observations on individuals each followed for  $T$  time periods, that also includes the  $T + 1$  observation  $X_{T+1}$  of the state variables, where  $W = (X'_1, Y_{21}, \dots, X'_T, Y_{2T}, X'_{T+1})'$ . An estimator of  $\theta_0$  can be obtained by constructing first step estimators  $\hat{\gamma}_2(x)$  and  $\hat{\gamma}_3$ , substituting these estimators for  $\gamma_2$  and  $\gamma_3$  in  $a(x, \theta, \gamma_2, \gamma_3)$  in equation (3.4), and then maximizing a binary choice log-likelihood as if  $\hat{\gamma}_2(x)$  and  $\hat{\gamma}_{30}$  were true. We specify as identifying moment functions the derivative of the pseudo log-likelihood associated with the binary choice probability in equation (3.4) with respect to  $\theta$ ,

$$g(W, \gamma, \theta) = \frac{1}{T} \sum_{t=1}^T D(X_t) \pi(a(X_t, \theta, \gamma_2, \gamma_3)) [Y_{2t} - \Lambda(a(X_t, \theta, \gamma_2, \gamma_3))],$$

$$\pi(a) = \frac{\Lambda_a(a)}{\Lambda(a)[1 - \Lambda(a)]}, \quad \Lambda_a(a) = \frac{d\Lambda(a)}{da}. \quad (3.5)$$

Estimators of  $\gamma_{10}(x)$ ,  $\gamma_{20}(x)$ , and  $\gamma_{30}$  are needed as a first step  $\hat{\gamma}_\ell$  for the identifying moment function. We will consider any  $\hat{\gamma}_{1\ell}(x)$  that converges sufficiently quickly in mean-square. For example,  $\hat{\gamma}_{1\ell}$  could be logit Lasso or a linear Lasso estimator with dependent variable  $Y_{2t}$ . We use Lasso to construct  $\hat{\gamma}_{2\ell}(x)$  in order to control for estimation error that results from an estimated dependent variable. Let  $\hat{\gamma}_{1\ell\ell'}(x)$  be an estimator of the conditional choice probability computed from observations not in  $I_\ell$  or  $I_{\ell'}$ . Let  $b(x)$  denote a  $p \times 1$  dictionary of functions of the state variables  $x$ . We form  $\hat{\gamma}_{2\ell}(x)$  and  $\hat{\gamma}_{3\ell}$  as

$$\hat{\gamma}_{2\ell}(x) = b(x)' \hat{\beta}_{2\ell},$$

$$\hat{\beta}_{2\ell} = \arg \min_{\beta} \left\{ -2\hat{M}'_{2\ell} \beta + \beta' \hat{Q}_{2\ell} \beta + 2r_1 \sum_{j=1}^p |\beta_j| \right\},$$

$$\hat{M}_{2\ell} = \frac{1}{(n - n_\ell)T} \sum_{\ell' \neq \ell} \sum_{i \in I_{\ell'}} \sum_{t=1}^T Y_{2it} b(X_{it}) H(\hat{\gamma}_{1\ell\ell'}(X_{i,t+1})),$$

$$\hat{Q}_{2\ell} = \frac{1}{(n - n_\ell)T} \sum_{i \notin I_\ell} \sum_{t=1}^T Y_{2it} b(X_{it}) b(X_{it})',$$

$$\hat{\gamma}_{3\ell} = \frac{1}{\hat{P}_1(n - n_\ell)T} \sum_{\ell' \neq \ell} \sum_{i \in I_{\ell'}} \sum_{t=1}^T Y_{1it} H(\hat{\gamma}_{1\ell\ell'}(X_{i,t+1})),$$

$$\hat{P}_1 = \frac{1}{(n - n_\ell)T} \sum_{i \notin I_\ell} \sum_{t=1}^T Y_{1it}.$$
(3.6)

Here  $\hat{\gamma}_{2\ell}(x)$  is Lasso with left-hand-side variable  $H(\hat{\gamma}_{1\ell\ell'}(X_{i,t+1}))$  and right-hand-side variables  $b(X_{it})Y_{2it}$ , and  $\hat{\gamma}_{3\ell}$  is a sample mean conditional on  $Y_{1it} = 1$ . Here  $\hat{\gamma}_{2\ell}$  and  $\hat{\gamma}_{3\ell}$  use all observations with  $i \notin I_\ell$ . The nested sample splitting in  $\hat{\gamma}_{1\ell\ell'}(x)$  is useful in only requiring mean-square convergence rates for conditional choice probabilities, although it is somewhat complicated. When  $L$  is of moderate size (e.g.,  $L = 5$ ), there may be many  $\hat{\gamma}_{1\ell\ell'}(x)$  to compute (e.g., 25), although an estimate for a particular  $\ell$  and  $\ell'$  could provide a good starting value for other splits.

This example is more complicated than Examples 1 and 2 in having multiple first steps. When there are multiple first steps, the FSIF is the sum of the FSIF's for each first step that is obtained while holding the other first steps fixed at their true value, as in Newey (1994a, p. 1357). Here there are three first steps,  $\hat{\gamma}_{1\ell}(x)$ ,  $\hat{\gamma}_{2\ell}(x)$ , and  $\hat{\gamma}_{3\ell}$ . Consequently, the FSIF is the sum of three terms, one term for each first step, given by

$$\begin{aligned}\phi(W, \gamma, \alpha, \theta) &= \phi_1(W, \gamma, \alpha, \theta) + \phi_2(W, \gamma, \alpha, \theta) + \phi_3(W, \gamma, \alpha), \\ \phi_1(W, \gamma, \alpha, \theta) &= \frac{1}{T} \sum_{t=1}^T \alpha_1(X_t, \theta) [Y_{2t} - \gamma_1(X_t)], \\ \phi_2(W, \gamma, \alpha, \theta) &= \frac{1}{T} \sum_{t=1}^T \alpha_2(X_t, Y_{2t}, \theta) [H(\gamma_1(X_{t+1})) - \gamma_2(X_t)], \\ \phi_3(W, \gamma, \alpha) &= \alpha_3 \frac{1}{T} \sum_{t=1}^T Y_{2t} \{H(\gamma_1(X_{t+1})) - \gamma_3\}.\end{aligned}$$

Viewing each of  $\hat{\gamma}_{1\ell}(x)$ ,  $\hat{\gamma}_{2\ell}(x)$ , and  $\hat{\gamma}_{3\ell}$  as nonparametric regressions, the form of each  $\phi_j(w, \gamma, \alpha, \theta)$  follows from Proposition 4 of Newey (1994a). The true functions  $\alpha_{10}$ ,  $\alpha_{20}$ , and  $\alpha_{30}$  are

$$\begin{aligned}\alpha_{10}(x, \theta_0) &= \{E[\alpha_{20}(X_t, Y_{2t}, \theta_0) | X_{t+1} = x] + \alpha_{30} E[Y_{1t} | X_{t+1} = x]\} H_p(\gamma_{10}(x)), \\ \alpha_{20}(x, y_2, \theta_0) &= -\delta D(x) \pi(a(x)) \frac{\Lambda_a(a(x)) y_2}{\Lambda(a(x))}, \quad a(x) = a(x, \theta_0, \gamma_{20}, \gamma_{30}), \\ \alpha_{30} &= -E[\alpha_{20}(X_t, Y_{2t}, \theta_0)] / P_{10}, P_{10} = E[Y_{1t}].\end{aligned}\tag{3.7}$$

In this example, we construct  $\hat{\alpha}_{2\ell}$ ,  $\hat{\alpha}_{3\ell}$ , and  $\hat{\alpha}_{1\ell}$  using the known form of the FSIF given here. We obtain an initial estimator  $\tilde{\theta}_\ell$  from binary choice pseudo maximum likelihood over  $i \notin I_\ell$ ,  $t \leq T$  with  $\gamma_2$  and  $\gamma_3$  replaced by  $\hat{\gamma}_{2\ell}$  and  $\hat{\gamma}_{3\ell}$  respectively in the choice probability formula. Also, let  $\hat{a}_{it} = a(X_{it}, \tilde{\theta}_\ell, \hat{\gamma}_{2\ell}, \hat{\gamma}_{3\ell})$  and construct  $\hat{\alpha}_{2\ell}(X_{it}, Y_{2it}, \tilde{\theta}_\ell)$  by substituting  $\hat{a}_{it}$  for  $a(x)$ ,  $X_{it}$  for  $x$ ,  $Y_{2it}$  for  $y_2$ , and  $\tilde{\theta}_\ell$  for  $\theta_0$  in the formula for  $\alpha_{20}(x, y_2, \theta_0)$  in equation (3.7). Next, obtain  $\hat{\alpha}_{3\ell}$  by replacing  $\alpha_{20}(X_t, Y_{2t}, \theta_0)$  by  $\hat{\alpha}_{2\ell}(X_{it}, Y_{2it}, \tilde{\theta}_\ell)$  and population expectations by sample averages over  $i \notin I_\ell$ ,  $t \leq T$  in the third line of equation (3.7). Also, obtain  $\hat{\alpha}_{1\ell}(x, \theta)$  by replacing  $\alpha_{30}$  and  $\gamma_{10}(x)$  by  $\hat{\alpha}_{3\ell}$  and  $\hat{\gamma}_{1\ell}(x)$  respectively in the first line of equation (3.7) and by replacing the two conditional expectations by the predicted values from Lasso regressions over  $i \notin I_\ell$ ,  $t \leq T$  with regressors  $b(X_{i,t+1})$ , dependent variables equal to each element of  $\hat{\alpha}_{2\ell}(X_{it}, Y_{2it}, \tilde{\theta}_\ell)$  and  $Y_{1it}$  respectively, and regularization factors  $r_2$  and  $r_3$  respectively, analogously to  $\hat{\gamma}_{2\ell}(x)$ . Finally, substitute  $\hat{\alpha}_{1\ell}$ ,  $\hat{\alpha}_{2\ell}$ , and  $\hat{\alpha}_{3\ell}$  for  $\alpha_{10}$ ,  $\alpha_{20}$ , and  $\alpha_{30}$  and  $\hat{\gamma}_{1\ell}$ ,  $\hat{\gamma}_{2\ell}$ , and  $\hat{\gamma}_{3\ell}$  for  $\gamma_1$ ,  $\gamma_2$ , and  $\gamma_3$  in the formulas for  $\phi_1$ ,  $\phi_2$ , and  $\phi_3$  and construct a debiased GMM estimator as in Section 2.1.

To explore the finite sample properties of this estimator, we carried out a Monte Carlo study for a model similar to that of Rust (1987). The state variables consisted of a positive variable  $x_1$  (mileage) and other variables  $x_2, \dots, x_6$  with transition

$$X_{1,t+1} = 1 + 1(Y_{2t} = 1)X_{1t} + S_{t+1}^2,$$

$$S_{t+1}|X_t \sim N\left(0.2 + \sum_{k=1}^5 c_k X_{t,k+1}, 1\right),$$

$$c = (0.1, 0.025, 0.0111, 0.0063, 0.004),$$

where  $(X_{2t}, \dots, X_{6t})$  is i.i.d. over  $t$ ,  $X_{2t}$ ,  $X_{4t}$ , and  $X_{6t}$  are chi-squared with one degree of freedom, and  $X_{3t}$  and  $X_{5t}$  are binary with  $\Pr(X_{kt} = 1) = 1/2$ ,  $k = 3, 5$ . We specified that  $D(x)$  is two-dimensional with  $D_1(x) = (-1, 0)'$  and  $D_2(x) = (0, \sqrt{x_1})'$  and that  $\varepsilon_{1t}$ ,  $\varepsilon_{2t}$  are independent Type I extreme value, so that  $\Lambda(a) = e^a/(1 + e^a)$  corresponds to binary logit.

To generate the data, we solved the Bellman equation on a finite grid using the fact that the state space has a two-dimensional structure in terms of  $x_1$  and  $\sum_{k=1}^5 c_k x_{k+1}$ , with linear interpolation between grid points. We did not enforce this index structure in estimation, so that the estimation treated the state space as dimension six. We carry out 500 Monte Carlo replications for  $T = 10$  and  $n = 100, 300, 1000$ , and  $10,000$ . We specified five-fold cross-fitting where  $L = 5$ . We consider three specifications of the vector  $b(x)$  used by Lasso, consisting of (a) the elements of  $x$ , (b) those from (a) and squares of elements of  $x$ ; (c) those from (b) and all products of two elements of  $x$ . The conditional choice probability estimators  $\hat{\gamma}_{1\ell, v}(x)$  and  $\hat{\gamma}_{1\ell}(x)$  were logit Lasso trimmed to be between 0.0001 and 0.9999. We used the MATLAB Lasso and logit Lasso procedures for computation. The regularization values  $r_1$ ,  $r_2$ , and  $r_3$  for each Lasso were chosen by two-fold cross-validation. Although we do not know whether the resulting  $r$ 's satisfy the conditions in the asymptotic theory of Section 6, we do this so that the estimator in the Monte Carlo is based on an "off the shelf" machine learner of unknown functions.

The results are reported in Tables I, II, and III. The PI labels the plug-in GMM estimator based only on identifying moment functions, DB the debiased GMM, Bias is the absolute value of bias, Med SE denotes the median of the estimated standard errors corresponding to equation (2.8), SD denotes standard deviation, and Cvg denotes coverage probability of a nominal 95 percent confidence interval.

In all cases, debiased GMM has much smaller bias than the plug-in estimator. For the richest dictionary  $b(X)$  of Table III, coverage probabilities are quite close to the nominal value though conservative. For the less rich dictionaries of Tables I and II, enough bias remains relative to variance that coverage probabilities are far from their nominal values for the largest sample size. In contrast, plug-in GMM has large bias and confidence interval coverage probabilities that are far from their nominal values in all cases. Remarkably, for larger sample sizes or smaller dimensional  $b(x)$ , debiased GMM is no more variable

than plug-in GMM, and in several cases is less variable. Overall, the performance of the debiased GMM estimator in this example with an “off the shelf” machine learner suggests that debiased GMM for dynamic discrete choice and other structural models could be useful in practice.

An alternative debiased GMM estimator could be obtained by taking the plim’s of  $\hat{\gamma}_1$  and  $\hat{\gamma}_2$  to be least squares projections that solve equation (2.10) for corresponding residuals and using automatic debiasing like that described in Section 2.3. Monte Carlo examples in other settings, such as Singh and Sun (2019), find that approach delivers estimators and standard errors with good finite sample properties. We intend to consider this approach to debiased GMM for dynamic discrete choice in future work.

4. ORTHOGONALITY

To show the orthogonality conditions of equations (2.4) and (2.5), we begin with a simpler, more basic result. We assume that equation (2.2) is satisfied for all  $F_0$  in some set  $\mathcal{F}$  and for  $\theta \in \Theta$ . For  $F \in \mathcal{F}$ , let  $\alpha(F)$  denote  $\alpha_0$  such that equation (2.2) is satisfied when  $F_0 = F$ , that is, when  $F$  is the CDF of  $W$ . Note that  $\alpha_0 = \alpha(F_0)$ . Also let

$$\bar{\psi}(\gamma, \alpha, \theta) := E[\psi(W, \gamma, \alpha, \theta)].$$

Because  $\phi(w, \gamma, \alpha, \theta)$  is the FSIF, it will satisfy the mean zero condition in equation (2.2) identically in  $F$ , so that  $0 \equiv E_F[\phi(W, \gamma(F), \alpha(F), \theta)]$ . Substituting  $F_\tau = (1 - \tau)F_0 + \tau H$

for  $F$  and differentiating this identity with respect to  $\tau$  at  $\tau = 0$  gives

$$\begin{aligned} 0 &= \int \phi(w, \gamma_0, \alpha_0, \theta) H(dw) + \frac{\partial}{\partial \tau} E[\phi(W, \gamma(F_\tau), \alpha(F_\tau), \theta)] \\ &= \frac{\partial}{\partial \tau} E[g(W, \gamma(F_\tau), \theta)] + \frac{\partial}{\partial \tau} E[\phi(W, \gamma(F_\tau), \alpha(F_\tau), \theta)] \\ &= \frac{\partial}{\partial \tau} \bar{\psi}(\gamma(F_\tau), \alpha(F_\tau), \theta), \end{aligned} \quad (4.1)$$

where the first and third equalities follow by the chain rule and the second equality follows from the influence function formula in equation (2.2). This equation shows that the functions  $\gamma$  and  $\alpha$  have no first-order effect on  $\bar{\psi}(\gamma, \alpha, \theta)$  along the path  $(\gamma(F_\tau), \alpha(F_\tau))$ . The second equality shows how the presence of  $E[\phi(W, \gamma, \alpha, \theta)]$  “partials out” the effect of varying  $\tau$  on  $E[g(W, \gamma(F_\tau), \theta)]$ . The zero mean property of the FSIF implies that the local effect of  $\gamma$  on  $E[g(W, \gamma, \theta_0)]$  along the path  $\gamma(F_\tau)$  is cancelled, or “partialled out,” by the effect of varying  $\gamma$  and  $\alpha$  on  $E[\phi(W, \gamma, \alpha, \theta)]$  along the path  $(\gamma(F_\tau), \alpha(F_\tau))$ . The following result gives precise conditions for equation (4.1):

**THEOREM 1:** *If, for any  $\theta \in \Theta$ , (i) equation (2.2) is satisfied, (ii)  $\int \phi(w, \gamma(F_\tau), \alpha(F_\tau), \theta) F_\tau(dw) = 0$  for all  $\tau \in [0, \bar{\tau}]$  with  $\bar{\tau} > 0$ , and (iii)  $\int \phi(w, \gamma(F_\tau), \alpha(F_\tau), \theta) F_0(dw)$  and  $\int \phi(w, \gamma(F_\tau), \alpha(F_\tau), \theta) H(dw)$  are continuous at  $\tau = 0$ , then equation (4.1) is satisfied.*

The proofs of this result, Theorems 2–7, and Lemma 8 are given in Appendix A.

**EXAMPLE 1—continued:** Here  $g(w, \gamma, \theta) = z\gamma(x) - \theta$  and  $\phi(w, \gamma, \alpha) = \alpha(x)[y - \gamma(x)]$  so that, by equation (2.1),

$$\begin{aligned} \bar{\psi}(\gamma, \alpha, \theta) &= E[Z\gamma(X)] - \theta + E[\alpha(X)\{Y - \gamma(X)\}] \\ &= \theta_0 - \theta - E[\{\alpha(X) - \alpha_0(X)\}\{\gamma(X) - \gamma_0(X)\}]. \end{aligned}$$

When  $\alpha(X) = \alpha_0(X)$ , the presence of  $\gamma$  in the identifying moment  $E[g(W, \gamma, \theta)]$  is exactly cancelled, or partialled out, by the presence of  $\gamma$  in  $E[\phi(W, \gamma, \alpha_0)] = E[\alpha_0(X)\{\gamma_0(X) - \gamma(X)\}]$ , so that variation in  $\gamma$  has no effect.

Equation (4.1) is a zero total derivative condition for joint variation in  $(\gamma, \alpha)$  along the path  $(\gamma(F_\tau), \alpha(F_\tau))$ . In many cases,  $\gamma(F)$  and  $\alpha(F)$  are distinct objects so that it is possible to choose  $F_\tau$  so that  $\alpha(F_\tau)$  varies with  $\tau$  and  $\gamma(F_\tau) = \gamma_0$  remains equal to its true value. For example,  $\gamma(F)$  and  $\alpha(F)$  may be determined by the distributions of different random variables and so be distinct objects. In such cases, equation (2.2) implies the orthogonality property of equation (2.5).

**THEOREM 2:** *For any  $\alpha \in \mathcal{A}$  and  $\theta \in \Theta$ , if (i) there is  $F_\alpha$  such that  $\alpha(F_\alpha) = \alpha$  and  $\gamma(F_\tau^\alpha) = \gamma_0$  for  $F_\tau^\alpha = (1 - \tau)F_\alpha + \tau F_0$  and all  $\tau$  small enough, and (ii)  $d \int g(w, \gamma(F_\tau^\alpha), \theta) F_\alpha(dw) / d\tau = \int \phi(w, \gamma_0, \alpha, \theta) F_0(dw)$ , then*

$$E[\phi(W, \gamma_0, \alpha, \theta)] = 0. \quad (4.2)$$

Note that hypothesis (ii) is just the characterization of the FSIF in equation (2.2) when the true distribution is  $F_\alpha$  and  $H$  is set equal to  $F_0$ . Thus, Theorem 2 shows that equation

(2.5) is satisfied at every  $\theta \in \Theta$  and every  $\alpha$  such that there is some distribution  $F_\alpha$  such that  $\alpha = \alpha(F_\alpha)$  and  $\gamma(F_\tau^\alpha) = \gamma_0$  for all  $\tau$  close enough to zero. In all the examples of which we are aware, equation (4.2) is easy to confirm by inspection of  $\phi(W, \gamma_0, \alpha, \theta)$ .

EXAMPLE 1—continued: Here  $E[\phi(W, \gamma_0, \alpha, \theta)] = E[\alpha(X)\{Y - \gamma_0(X)\}] = 0$  for any  $\alpha(X)$  by  $\gamma_0(X) = E[Y|X]$  and iterated expectations.

Theorem 2 shows that equation (2.5) is a general property of the FSIF and is not confined to a particular set of examples.

The orthogonality property of equation (2.4) will follow from Theorem 1 when  $F_\tau$  can be specified so that  $\alpha(F_\tau) = \alpha_0$  and some regularity conditions are satisfied. In that case, equation (4.1) implies  $\partial \bar{\psi}(\gamma(F_\tau), \alpha_0, \theta)/\partial \tau = 0$ . As in the discussion preceding Theorem 2, choosing  $F_\tau$  in this way will generally be possible when  $\gamma(F)$  and  $\alpha(F)$  are distinct objects depending on distinct features of  $F$ . Equation (2.4) then will follow if the set of pathwise derivatives  $d\gamma(F_\tau)/d\tau$  is well defined and rich enough and the chain rule can be applied, as it can under Hadamard differentiability of  $\bar{\psi}(\gamma, \alpha_0, \theta)$  in  $\gamma$  and  $\gamma(F_\tau)$  in  $\tau$ .

THEOREM 3: *If there is a norm  $\|\gamma\|$ , a linear set  $\Gamma$ , and a set  $\mathcal{H}$  such that, for all  $H \in \mathcal{H}$ : (i)  $\alpha(F_\tau) = \alpha_0$  for all  $\tau$  small enough and equation (4.1) is satisfied; (ii)  $\bar{\psi}(\gamma, \alpha_0, \theta)$  is Hadamard differentiable at  $\gamma_0$  tangentially to  $\Gamma$ ; (iii)  $\gamma(F_\tau)$  is Hadamard differentiable at  $\tau = 0$ ; (iv) the closure of  $\{\partial \gamma(F_\tau)/\partial \tau : H \in \mathcal{H}\}$  is  $\Gamma$ , then*

$$\frac{\partial}{\partial t} \bar{\psi}(\gamma_0 + t\delta, \alpha_0, \theta)|_{t=0} = 0 \quad \text{for all } \delta \in \Gamma. \quad (4.3)$$

Furthermore, if  $\bar{\psi}(\gamma, \alpha_0, \theta_0)$  is twice continuously Frechet differentiable in a neighborhood of  $\gamma_0$ , then there is  $C > 0$  such that for  $\|\gamma - \gamma_0\|$  small enough,

$$\|\bar{\psi}(\gamma, \alpha_0, \theta_0)\| \leq C\|\gamma - \gamma_0\|^2. \quad (4.4)$$

Hadamard and Frechet differentiability are defined and discussed, for example, in van der Vaart (1998, 20.2). The first conclusion of this result is the orthogonality condition of equation (2.4). Thus, Theorems 2 and 3 combined show that adding the FSIF  $\phi(w, \gamma, \alpha, \theta)$  to identifying moment functions  $g(w, \gamma, \theta)$  is a construction such that  $\psi(w, \gamma, \alpha, \theta) = g(w, \gamma, \theta) + \phi(w, \gamma, \alpha, \theta)$  satisfies the orthogonality conditions of equations (2.4) and (2.5).

The second conclusion of Theorem 3, given as equation (4.4), bounds the departure from zero of the expected moment functions as just  $\gamma$  varies. This bound is useful for formulating regularity conditions for root- $n$  consistency of debiased GMM when  $\bar{\psi}(\gamma, \alpha_0, \theta_0)$  is nonlinear in  $\gamma$ , as explained in Section 6. When formulating regularity conditions for particular moment functions and first step estimators, it may be simpler to directly confirm equation (4.4). In many cases, equation (4.4) will be satisfied under specific regularity conditions when  $\|a\|$  is a mean-square norm  $\|a\| = \sqrt{E[a(W)^2]}$ . Equation (4.4) with a mean-square norm  $\|\gamma - \gamma_0\|$  has wide applicability to machine learning first steps where mean-square convergence rates are available.

If  $\gamma$  were taken to be the limit of a nonparametric estimator  $\hat{\gamma}$  for fixed bandwidth, number of series terms, or regularization, then we can think of  $\|\gamma - \gamma_0\|$  as bias in  $\gamma$  from nonparametric estimation. Frechet differentiability of  $\bar{\psi}(\gamma, \alpha_0, \theta_0)$  in  $\gamma$  and equation (4.4) then imply that  $\bar{\psi}(\gamma, \alpha_0, \theta_0) = o(\|\gamma - \gamma_0\|)$ , so that the orthogonal moments  $\bar{\psi}(\gamma, \alpha_0, \theta_0)$  shrink to zero faster than the nonparametric bias. Thus, the orthogonal moment functions

constructed here have the small bias property considered in Newey, Hsieh, and Robins (1998, 2004). As usual for GMM, the estimator  $\hat{\theta}$  will inherit this property of the orthogonal moment functions.

The construction of orthogonal moment functions we consider has antecedents in the literature on functional estimation, where the identifying moment conditions are  $g(w, \gamma, \theta) = m(\gamma) - \theta$  for some explicit functional of  $m(\gamma)$  of  $\gamma$ . Here  $\phi(w, \gamma, \alpha)$  is the influence function of  $m(\gamma(F))$  and  $\psi(w, \gamma, \alpha, \theta) = m(\gamma) - \theta + \phi(w, \gamma, \alpha)$ . Such orthogonal moment functions when  $\gamma$  is a pdf were given by Hasminskii and Ibragimov (1978), Pfanzagl and Wefelmeyer (1982), and Bickel and Ritov (1988). Newey, Hsieh, and Robins (1998, 2004) generalized this construction to allow  $m(w, \gamma)$  to depend on  $w$ , to  $\gamma$  that is a product of a pdf and conditional mean, and to  $\gamma = F$ . Robins, Li, Tchetgen Tchetgen, and van der Vaart (2008) gave similar constructions. The construction given here for any  $\gamma$  was also described in Chernozhukov et al. (2018) and Bravo, Escanciano, and van Keilegom (2020) and originated in the joint research for this paper.

Equation (4.1) is similar to Theorem 2.2 of Robins, Li, Tchetgen Tchetgen, and van der Vaart (2008) but different in applying directly to the standard influence function characterization in equation (2.2) without specifying a score function (derivative of the log-likelihood of a model). Proceeding in this way allows us to show orthogonality of  $\psi(w, \gamma, \alpha, \theta)$  using equation (4.1). To the best of our knowledge, equation (4.1) has not appeared in this form previously. Also, Theorem 2 and Theorem 3, for any first step  $\gamma$ , were not shown in any previous work of which we are aware. These results are distinguished from Newey, Hsieh, and Robins (1998, 2004) and Robins, Li, Tchetgen Tchetgen, and van der Vaart (2008, 2013) in the conclusion of Theorem 2 and in providing, for any first step  $\gamma$ , key regularity conditions used in the asymptotic theory of Section 6.

The orthogonalization given here is estimator based rather than model based, relying only on  $g(w, \gamma, \theta)$  and the plim  $\gamma(F)$  of  $\hat{\gamma}$  under general misspecification and not on the specification of a model. The behavior of the sample moments under misspecification is fully accounted for by using the plim  $\gamma(F)$  of  $\hat{\gamma}$  under general misspecification in the construction of the orthogonal moment functions. Consequently, standard errors will be robust to misspecification when the number of moment functions and parameters of interest is the same.

There are also model based approaches to construction of orthogonal moment functions. Efficient scores and influence functions for semiparametric models are known to be orthogonal for first steps corresponding to those in the model, as in Bickel, Klaassen, Ritov, and Wellner (1993) and van der Vaart (1998). More generally, the residual from the projection of identifying moment functions on the tangent set is orthogonal for first steps corresponding to those in the model, as in Newey (1990). The orthogonality of such moment functions is sensitive to model misspecification unless the model is nonparametric. Also, orthogonality is sensitive to using first step estimators of precisely the objects specified in the model, as pointed out by van der Laan (2014) and Vermeulen and Vansteelandt (2015).

The construction we give bypasses the semiparametric efficiency framework and is based on the simpler influence function characterization in equation (2.2) and the limit  $\gamma(F)$  for any semiparametric estimator as in Newey (1994a). This construction highlights the distinct roles of  $g(w, \gamma, \theta)$  as identifying moments and  $\phi(w, \gamma, \alpha, \theta)$  as a bias correction that does not affect identification and is entirely determined by  $g(w, \gamma, \theta)$  and  $\gamma(F)$ . The distinct role of  $\phi(w, \gamma, \alpha, \theta)$  leads directly to Theorem 2 and motivates the automatic estimation of  $\alpha_0$  in Section 2. For these reasons, we describe the orthogonal moment construction as adding the FSIF to identifying moments rather than finding an efficient influence function.

The orthogonal moment functions we give are nonparametric, efficient influence functions for a special object, the plim of the identifying moment functions evaluated at  $\gamma(F)$ , that is,  $E_F[g(W, \gamma(F), \theta)]$ . This object is nonparametric and so it has a unique influence function, as in [van der Vaart \(1991\)](#) and [Newey \(1994a\)](#). By differentiating  $E_{F_\tau}[g(W, \gamma(F_\tau), \theta_0)]$  with respect to  $\tau$ , applying the chain rule, and using (2.2), it follows that the influence function of this object at  $F_0$  is  $\psi(W, \gamma_0, \alpha_0, \theta_0)$  under the moment condition  $E[g(W, \gamma_0, \theta_0)] = 0$ . The sample average of the debiased moment function  $\hat{\psi}(\theta_0)$  is a nonparametric estimator of  $E_F[g(W, \gamma(F), \theta_0)]$ . If  $\hat{\psi}(\theta_0)$  is asymptotically equivalent to a sample average and locally regular, meaning that for  $H$  and data that are i.i.d. with CDF  $F_{\tau_n} = (1 - \tau_n)F_0 + \tau_n H$  and  $\tau_n = O(1/\sqrt{n})$  the limiting distribution of  $\sqrt{n}\{\hat{\psi}(\theta_0) - E_{F_{\tau_n}}[g(W, \gamma(F_{\tau_n}), \theta_0)]\}$  does not depend on  $\tau_n$ , then uniqueness of the influence function for a nonparametric object implies

$$\begin{aligned} & \frac{1}{n} \sum_{\ell=1}^L \sum_{i \in I_\ell} [g(W_i, \hat{\gamma}_\ell, \theta_0) + \phi(W_i, \hat{\gamma}_\ell, \hat{\alpha}_\ell, \tilde{\theta}_\ell)] \\ &= \hat{\psi}(\theta_0) = \frac{1}{n} \sum_{i=1}^n \psi(W_i, \gamma_0, \alpha_0, \theta_0) + o_p(n^{-1/2}), \end{aligned} \quad (4.5)$$

That is, the *only* sample average of a function of the data that  $\hat{\psi}(\theta_0)$  can be asymptotically equivalent to, and also be locally regular, is  $\sum_{i=1}^n \psi(W_i, \gamma_0, \alpha_0, \theta_0)/n$ . Equation (4.5) is precisely an asymptotic version of orthogonality where the sample average  $\hat{\psi}(\theta_0)$  is asymptotically equivalent to the sample average of the same function with estimators  $\hat{\gamma}_\ell$ ,  $\hat{\alpha}_\ell$ , and  $\tilde{\theta}_\ell$  replaced by their limits. In this standard way, orthogonality of  $\psi(W_i, \gamma_0, \alpha_0, \theta_0)$  can be understood as resulting from  $\psi(W_i, \gamma_0, \alpha_0, \theta_0)$  being the efficient influence function of the nonparametric object  $E_F[g(W, \gamma(F), \theta)]$  evaluated at the plim  $\gamma(F)$  of the first step.

In some cases, the identifying moment functions  $g(w, \gamma, \theta)$  may already be orthogonal, so that  $\phi(w, \gamma, \alpha, \theta) = 0$ . An important class of orthogonal moment functions are those where  $g(w, \gamma, \theta)$  is the derivative with respect to  $\theta$  of an objective function where nonparametric parts have been concentrated out. This class of moment functions includes those of [Robinson \(1988\)](#), [Ichimura \(1993\)](#), [Klein and Spady \(1993\)](#), and various partially linear regression models where  $\gamma$  represents a conditional expectation. It also includes the efficient score for a semiparametric model when the nonparametric component estimates the maximizer of the expected log-likelihood; see [Newey \(1994a, pp. 1358–1359\)](#) and [van der Vaart \(1998, pp. 391–396\)](#). In general, suppose that there is a function  $q(w, \theta, \zeta)$  such that  $g(w, \gamma, \theta) = \partial q(w, \theta, \zeta(\theta))/\partial \theta$  and  $\zeta(\theta) = \arg \max_{\zeta} E[q(W, \theta, \zeta)]$ , where  $\gamma$  includes  $\zeta(\theta)$  and possibly additional functions. Proposition 2 of [Newey \(1994a\)](#) and Lemma 2.5 of [Chernozhukov et al. \(2018\)](#) then imply that  $g(w, \gamma, \theta)$  is orthogonal.

## 5. DOUBLE ROBUSTNESS

The zero derivative condition in equation (2.4) is an appealing robustness property. This condition can be interpreted as local insensitivity of the average moments  $\bar{\psi}(\gamma, \alpha_0, \theta) = E[\psi(W, \gamma, \alpha_0, \theta)]$  to  $\gamma$ , with  $\bar{\psi}(\gamma, \alpha_0, \theta)$  varying little as  $\gamma$  varies away from  $\gamma_0$ . Because it is difficult to get unknown functions exactly right, especially in high dimensional settings, this property is an appealing one.

Such robustness considerations, well explained in [Robins and Rotnitzky \(2001\)](#), have motivated the development of doubly robust moment functions that have expectation that does not depend on one first step if the other first step is set equal to its plim. Doubly robust moment conditions allow two chances for identifying moment conditions to hold, an appealing robustness feature. Also, doubly robust moment conditions have simpler conditions for asymptotic normality than general debiased GMM, as discussed in [Section 6](#).

In this section, we characterize double robustness and derive several novel classes of doubly robust moment functions. We construct doubly robust moment functions by adding to identifying moment functions the FSIF. In this way, the derivation of new doubly robust moment functions is aided by the construction of orthogonal moment functions in [Section 2](#).

### 5.1. Characterizing Double Robustness

Double robustness is that, for all  $\gamma \in \Gamma$ ,  $\alpha \in \mathcal{A}$ , and  $\theta \in \Theta$ ,

$$\bar{\psi}(\gamma, \alpha_0, \theta) = \bar{\psi}(\gamma_0, \alpha_0, \theta) = \bar{\psi}(\gamma_0, \alpha, \theta), \quad (5.1)$$

where  $\Gamma$  is the set of possible plim's  $\gamma(F)$  that we continue to assume is linear. The second equality of equation (5.1) already follows from the conclusion of [Theorem 2](#) that implies

$$\bar{\psi}(\gamma_0, \alpha, \theta) = E[g(W, \gamma_0, \theta)] + E[\phi(W, \gamma_0, \alpha, \theta)] = E[g(W, \gamma_0, \theta)] = \bar{\psi}(\gamma_0, \alpha_0, \theta).$$

The first conclusion of [Theorem 3](#) gives a local version of the first equality in equation (5.1). If  $\bar{\psi}(\gamma, \alpha_0, \theta)$  is affine in  $\gamma$ , then this local property becomes global so that double robustness holds. Clearly, doubly robust moment conditions have  $\bar{\psi}(\gamma, \alpha_0, \theta)$  that is constant in  $\gamma$ , and therefore are affine, so that  $\bar{\psi}(\gamma, \alpha_0, \theta)$  being affine in  $\gamma$  and satisfying the first conclusion of [Theorem 3](#) is a complete characterization of double robustness.

**THEOREM 4:**  $\psi(w, \gamma, \alpha, \theta)$  is doubly robust if and only if  $\bar{\psi}(\gamma, \alpha_0, \theta)$  is affine in  $\gamma$  and

$$\left. \frac{d\bar{\psi}(\gamma_0 + t\delta, \alpha_0, \theta)}{dt} \right|_{t=0} = 0 \quad \text{for all } \delta \in \Gamma.$$

This characterization can be used to construct doubly robust moment functions. A good place to start is an identifying moment function  $g(w, \gamma, \theta)$  that is affine in  $\gamma$ . If the associated FSIF  $\phi(w, \gamma, \alpha, \theta)$  is also affine in  $\gamma$ , then the orthogonal moment function  $\psi(w, \gamma, \alpha, \theta) = g(w, \gamma, \theta) + \phi(w, \gamma, \alpha, \theta)$  will be affine in  $\gamma$  and so be doubly robust, since the second condition of [Theorem 4](#) is satisfied by [Theorem 3](#). In the remainder of this section, we use [Theorem 4](#) to construct a variety of doubly robust moment functions.

[Robins and Rotnitzky \(2001\)](#) gave conditions for the existence of doubly robust moment functions in semiparametric models. [Theorem 4](#) is complementary to those results in giving a characterization of doubly robust moment functions.

### 5.2. Double Robustness for Regression First Steps

An important set of examples are those with  $\theta_0 = E[m(W, \gamma_0)]$  where  $m(W, \gamma)$  is linear in  $\gamma$ ,

$$\gamma(F) = \arg \min_{\gamma \in \Gamma} E_F[\{Y - \gamma(X)\}^2],$$

and  $\Gamma$  is a linear set of functions that is closed in mean-square (meaning  $\gamma \in \Gamma$  if, for every  $\varepsilon > 0$ , there exists  $\gamma_\varepsilon \in \Gamma$  with  $E[\{\gamma(X) - \gamma_\varepsilon(X)\}^2] < \varepsilon$ ). Here the identifying moment function is  $g(w, \gamma, \theta) = m(w, \gamma) - \theta$ , which is affine in  $\gamma$ . Also, by Proposition 4 of Newey (1994a), if there is  $\alpha_0(X) \in \Gamma$  with finite second moment such that  $E[m(W, \gamma)] = E[\alpha_0(X)\gamma(X)]$  for all  $\gamma \in \Gamma$ , the FSIF is

$$\phi(w, \gamma, \alpha) = \alpha(x)[y - \gamma(x)],$$

for  $\alpha \in \Gamma$ . Here the set  $\mathcal{A}$  of possible  $\alpha$  is  $\Gamma$ . By  $m(w, \gamma)$  and  $\phi(w, \gamma, \alpha)$  both affine in  $\gamma$ , Theorem 4 gives the following:

**THEOREM 5:** *If  $m(w, \gamma)$  is linear in  $\gamma \in \Gamma$  and there is  $\alpha_0 \in \Gamma$  such that  $E[m(W, \gamma)] = E[\alpha_0(X)\gamma(X)]$  for all  $\gamma \in \Gamma$ , then  $\psi(w, \gamma, \alpha, \theta) = m(w, \gamma) - \theta + \alpha(x)[y - \gamma(x)]$  is doubly robust.*

Existence of  $\alpha_0(x)$  in Theorem 5 is guaranteed by the Riesz representation theorem if  $E[m(W, \gamma)]$  is mean-square continuous in  $\gamma$ , so we refer to  $\alpha_0(x)$  as the Riesz representer. In Example 1, note that  $\psi(w, \gamma, \alpha, \theta) = Z\gamma(X) + Y\alpha(X) - \alpha(X)\gamma(X) - \theta$  is doubly robust by Theorem 5. Many important doubly robust moment functions are special cases of Theorem 5, including average treatment effects, policy effects, and average derivatives, as discussed in Newey and Robins (2017), Chernozhukov, Newey, and Robins (2018), Hirshberg and Wager (2019), and Chernozhukov, Newey, and Singh (2018). In these papers, a variety of other doubly robust moment functions are also formulated based on Theorem 5.

### 5.3. Double Robustness for Nonparametric IV

A larger set of important examples are those where the first step minimizes a population two-stage least squares objective function based on an affine residual. Let  $\lambda(W, \gamma)$  denote a scalar residual function that is affine in  $\gamma$ ,  $\mathcal{B} = \{b(X)\}$  denote a linear set of possible instrumental variables  $b(X)$  that is closed in mean-square, and  $\text{proj}_F(a(W)|\mathcal{S})$  denote the least squares projection of  $a(W)$  on a set  $\mathcal{S}$  that is linear and closed in mean-square when  $F$  is the true CDF. We consider debiased GMM where the plim of  $\hat{\gamma}$  is

$$\gamma(F) = \arg \min_{\gamma \in \Gamma} E_F[\text{proj}_F(\lambda(W, \gamma)|\mathcal{B})^2]. \quad (5.2)$$

This  $\gamma(F)$  is the plim of the nonparametric 2SLS estimator of Newey and Powell (2003), Newey (1991), and Ai and Chen (2003). It follows from Ai and Chen (2007, p. 40) and Ichimura and Newey (2021) that when  $E[\lambda(W, \gamma_0)b(X)] = 0$  for all  $b \in \mathcal{B}$ , which we assume, and certain other conditions are satisfied, then the FSIF has the form

$$\phi(w, \gamma, \alpha, \theta) = \alpha(x, \theta)\lambda(w, \gamma), \quad \alpha(x, \theta) \in \mathcal{B}.$$

It will follow from Theorem 4 that if the identifying moment function  $g(w, \gamma, \theta)$  and the residual  $\lambda(w, \gamma)$  are affine in  $\gamma$  on a linear set  $\Gamma$  that is closed in mean-square, then the orthogonal moment function

$$\psi(w, \gamma, \alpha, \theta) = g(w, \gamma, \theta) + \alpha(x, \theta)\lambda(w, \gamma)$$

will be affine also, and so will be doubly robust.

A special case, that generalizes the linear regression functionals of Theorem 5 to allow for endogeneity, has  $\lambda(W, \gamma) = Y - \gamma(Z)$ . Let  $\mathcal{A}$  denote the mean-square closure of  $\{\text{proj}_{F_0}(\gamma(Z)|\mathcal{B}) : \gamma \in \Gamma\}$ .

**THEOREM 6:** *If (i)  $m(w, \gamma)$  is linear in  $\gamma$  and there is  $v_m(Z) \in \Gamma$  such that  $E[m(W, \gamma)] = E[v_m(Z)\gamma(Z)]$  for all  $\gamma \in \Gamma$ ; (ii) there exists  $b_m \in \mathcal{B}$  such that  $\text{proj}_{F_0}(b_m(X)|\Gamma) = v_m(Z)$ ; (iii)  $E[b(X)\{Y - \gamma_0(Z)\}] = 0$  for all  $b \in \mathcal{B}$ , then  $\psi(w, \gamma, \alpha, \theta) = m(w, \gamma) - \theta + \alpha(x)[y - \gamma(z)]$  is doubly robust for  $\alpha_0(X) = \text{proj}_{F_0}(b_m(X)|\mathcal{A})$ .*

Condition (i) is like the hypothesis that  $E[m(W, \gamma)] = E[\alpha_0(X)\gamma(X)]$  in Theorem 5, condition (ii) is similar to the Severini and Tripathi (2012) condition for root- $n$  consistent estimability of  $\theta_0$ , and (iii) is a correct specification condition.

**EXAMPLE 4:** Many novel doubly robust moment functions can be constructed based on Theorem 6, including policy effects and average derivatives. A weighted average derivative example has  $m(w, \gamma) = \bar{v}(z)\partial\gamma(z)/\partial z_1$  for some known weight  $\bar{v}(z)$  where  $\Gamma$  is all functions of  $Z$  with finite second moment. Integration by parts gives

$$E[m(W, \gamma)] = E[v_m(Z)\gamma(Z)], \quad v_m(Z) = -\frac{\partial\{f_0(Z)\bar{v}(Z)\}/\partial z_1}{f_0(Z)},$$

where  $f_0(z)$  is the marginal pdf of  $Z$ . Then, by Theorem 6, a doubly robust moment function is

$$\psi(w, \gamma, \alpha, \theta) = \bar{v}(z)\frac{\partial\gamma(z)}{\partial z_1} - \theta + \alpha(x)[y - \gamma(z)],$$

when there exists  $b_m(X)$  with  $v_m(Z) = E[b_m(X)|Z]$ . This is a doubly robust moment function that could be used to construct a doubly robust version of the plug-in estimator of Ai and Chen (2007).

Using Theorem 4 to construct doubly robust moment functions can depend on specifying  $\gamma$  to make  $g(w, \gamma, \theta)$  and  $\phi(w, \gamma, \alpha, \theta)$  affine in  $\gamma$ . We illustrate with a well-known example.

**EXAMPLE 5:** Suppose that the object of interest is  $\theta_0 = E[Y^*]$ , where  $Y = 1(D = 1)Y^*$  is observed for an observed completed data indicator  $D \in \{0, 1\}$  and the data are missing at random with  $E[Y^*|X, D = 1] = E[Y^*|X]$  for observed covariates  $X$ . Inverse probability weighting gives  $\theta_0 = E[DY/P_0(X)] = E[P_0(X)^{-1}E[DY|X]]$ , which is nonlinear in the unknown propensity score  $P_0(X) = \Pr(D = 1|X)$ . A corresponding affine in  $\gamma$  identifying moment function is  $g(w, \gamma, \theta) = g(w, \gamma, \theta) = \gamma(x)dy - \theta$  with true first step  $\gamma_0(X) = P_0(X)^{-1}$ . This  $\gamma_0$  minimizes the objective function in equation (5.2) at  $F = F_0$  for  $\lambda(w, \gamma) = 1 - \gamma(x)d$  that is affine in  $\gamma$  and  $\mathcal{B}$  equal to the set of all functions of  $X$  with finite second moment. Also, for  $\alpha_0(X) = E[Y|X, D = 1] = E[DY|X]\gamma_0(X)$ , we have

$$\begin{aligned} E[g(W, \gamma, \theta_0)] &= E[E[DY|X]\{\gamma(X) - \gamma_0(X)\}] \\ &= E[\alpha_0(X)\gamma_0(X)^{-1}\{\gamma(X) - \gamma_0(X)\}] \\ &= E[\alpha_0(X)\{\gamma(X)P_0(X) - 1\}] \end{aligned}$$

$$\begin{aligned}
 &= E[\alpha_0(X)\{\gamma(X)D - 1\}] \\
 &= -E[\alpha_0(X)\lambda(W, \gamma)].
 \end{aligned}$$

The doubly robust moment function from equation (5.3) is then  $\psi(w, \gamma, \alpha, \theta) = d\gamma(x)y - \theta + \alpha(x)(1 - \gamma(x)d)$ , which is the doubly robust moment function of [Robins, Rotnitzky, and Zhao \(1994\)](#). This example shows how a classic doubly robust moment function is a special case of Theorem 4, with moment condition that is affine in a first step  $\gamma$  for  $\gamma_0$  equal to the inverse propensity score.

#### 5.4. Double Robustness for Probability Density First Step

Another interesting class of doubly robust moment conditions are those where the first step  $\gamma$  is a pdf of a function  $X$  of the data observation  $W$ . By Proposition 5 of [Newey \(1994a\)](#), the first step influence function has the form

$$\phi(w, \gamma, \alpha, \theta) = \alpha(x, \theta) - \int \alpha(u, \theta)\gamma(u) du,$$

which is affine in  $\gamma$ . When the identifying moment function is affine, adding this FSIF gives a doubly robust moment function. For  $g(w, \gamma, \theta) = m(w, \gamma) - \theta$ , a double robustness result is the following:

**THEOREM 7:** *If  $m(W, \gamma)$  is linear in  $\gamma$  and there exist  $\alpha_0(x)$  with  $\int \alpha_0(u)^2 du < \infty$  and  $E[m(W, \gamma)] = \int \alpha_0(u)\gamma(u) du$  for all  $\gamma$  with  $\int \gamma(u)^2 du < \infty$ , then  $\psi(W, \gamma, \alpha, \theta) = m(W, \gamma) - \theta + \alpha(X) - \int \alpha(u)\gamma(u) du$  is doubly robust.*

Here  $\alpha_0(x)$  is the Riesz representer of Proposition 5 of [Newey \(1994a\)](#) for the Lebesgue inner product.

**EXAMPLE 6:** An example is the density weighted average derivative of [Powell, Stock, and Stoker \(1989\)](#), where  $g(w, \gamma, \theta) = -2y \cdot \partial\gamma(x)/\partial x - \theta$  and  $\alpha_0(x) = \partial\{E[Y|X = x]\gamma_0(x)\}/\partial x$ . Because  $g(w, \gamma, \theta)$  is affine in  $\gamma$ , Theorem 7 implies

$$\psi(W, \gamma, \alpha, \theta) = -2Y \frac{\partial\gamma(X)}{\partial x} - \theta + \alpha(X) - \int \alpha(u)\gamma(u) du$$

is doubly robust. Double robustness of this moment function seems to be a novel result.

Robustness results for multiple first steps can be obtained from simple extensions of Theorems 2–4. When  $\gamma$  is a  $S \times 1$  vector of first steps and each first step satisfies a distinct orthogonality condition or is a pdf, as in this Section, then there will be one FSIF  $\phi_s(w, \gamma_s, \alpha_s, \theta)$  for each distinct component  $\gamma_s$  of  $\gamma$  ( $s = 1, \dots, S$ ), obtained by letting  $\gamma_s$  vary holding all other components of  $\gamma$  fixed at the corresponding component of  $\gamma_0$ . The orthogonal moment function is then

$$\psi(w, \gamma, \alpha, \theta) = g(w, \gamma, \theta) + \sum_{s=1}^S \phi_s(w, \gamma_s, \alpha_s, \theta).$$

Each FSIF will satisfy  $E[\phi_s(W, \gamma_{s0}, \alpha_s, \theta)] = 0$  identically in  $\alpha_s$  and  $\theta$  by Theorem 2. Consider varying  $\gamma_s$  while  $\gamma_{\tilde{s}} = \gamma_{\tilde{s}0}$  for each  $\tilde{s} \neq s$ . Then  $g(w, \gamma, \theta) + \phi_s(w, \gamma_s, \alpha_{s0}, \theta)$

will satisfy Theorem 3 as  $\gamma_s$  varies, and by Theorem 4,  $E[g(W, \gamma, \theta) + \phi_s(W, \gamma_s, \alpha_{s0}, \theta)]$  does not vary with  $\gamma_s$  if and only if  $E[g(W, \gamma, \theta) + \phi_s(W, \gamma_s, \alpha_{s0}, \theta)]$  is affine in  $\gamma_s$ . Thus  $\psi(w, \gamma, \alpha, \theta)$  will be multiply robust in the sense that  $E[\psi(W, \gamma_0, \alpha, \theta_0)] = 0$  for any  $\alpha$  and  $E[\psi(W, \gamma, \alpha_0, \theta_0)] = 0$  as  $\gamma_s$  varies holding all other components of  $\gamma$  fixed at their plims under the affine condition of the preceding sentence. These multiple robustness features generalize those of Tchetgen Tchetgen (2009) to the orthogonal moment functions we consider.

Doubly robust moment functions also can be used for identification of the parameter of interest  $\theta_0$ , for example, as in Escanciano and Li (2021).

## 6. ASYMPTOTIC THEORY

In this section, we give simple and general asymptotic theory for debiased GMM. We begin with conditions for the key property

$$\sqrt{n}\hat{\psi}(\theta_0) = \frac{1}{\sqrt{n}} \sum_{i=1}^n \psi(W_i, \theta_0, \gamma_0, \alpha_0) + o_p(1). \quad (6.1)$$

ASSUMPTION 1:  $E[\|\psi(W, \theta_0, \gamma_0, \alpha_0)\|^2] < \infty$  and

- (i)  $\int \|g(w, \hat{\gamma}_\ell, \theta_0) - g(w, \gamma_0, \theta_0)\|^2 F_0(dw) \xrightarrow{p} 0,$
- (ii)  $\int \|\phi(w, \hat{\gamma}_\ell, \alpha_0, \theta_0) - \phi(w, \gamma_0, \alpha_0, \theta_0)\|^2 F_0(dw) \xrightarrow{p} 0,$
- (iii)  $\int \|\phi(w, \gamma_0, \hat{\alpha}_\ell, \tilde{\theta}_\ell) - \phi(w, \gamma_0, \alpha_0, \theta_0)\|^2 F_0(dw) \xrightarrow{p} 0.$

These are mild mean-square consistency conditions for  $\hat{\gamma}_\ell$  and  $(\hat{\alpha}_\ell, \tilde{\theta}_\ell)$  separately. Let

$$\hat{\Delta}_\ell(w) := \phi(w, \hat{\gamma}_\ell, \hat{\alpha}_\ell, \tilde{\theta}_\ell) - \phi(w, \gamma_0, \hat{\alpha}_\ell, \tilde{\theta}_\ell) - \phi(w, \hat{\gamma}_\ell, \alpha_0, \theta_0) + \phi(w, \gamma_0, \alpha_0, \theta_0).$$

ASSUMPTION 2: For each  $\ell = 1, \dots, L$ , either (i)

$$\sqrt{n} \int \hat{\Delta}_\ell(w) F_0(dw) \xrightarrow{p} 0, \quad \int \|\hat{\Delta}_\ell(w)\|^2 F_0(dw) \xrightarrow{p} 0,$$

or (ii)  $\sum_{i \in I_\ell} \|\hat{\Delta}_\ell(W_i)\|/\sqrt{n} \xrightarrow{p} 0$ , or (iii)  $\sum_{i \in I_\ell} \hat{\Delta}_\ell(W_i)/\sqrt{n} \xrightarrow{p} 0$ .

This condition imposes a rate condition on the interaction remainder  $\hat{\Delta}_\ell(w)$ , that its average must go to zero faster than  $1/\sqrt{n}$ . Condition (iii) is a minimal regularity condition that is used in Newey and Robins (2017).

ASSUMPTION 3: For each  $\ell = 1, \dots, L$ , (i)  $\int \phi(w, \gamma_0, \hat{\alpha}_\ell, \tilde{\theta}_\ell) F_0(dw) = 0$  with probability approaching 1; and either (ii)  $\bar{\psi}(\gamma, \alpha_0, \theta_0)$  is affine in  $\gamma$ ; or (iii)  $\|\hat{\gamma}_\ell - \gamma_0\| = o_p(n^{-1/4})$  and  $\|\bar{\psi}(\gamma, \alpha_0, \theta_0)\| \leq C\|\gamma - \gamma_0\|^2$  for all  $\gamma$  with  $\|\gamma - \gamma_0\|$  small enough; or (iv)  $\sqrt{n}\bar{\psi}(\hat{\gamma}_\ell, \alpha_0, \theta_0) \xrightarrow{p} 0$ .

Assumption 3 incorporates Theorem 2 in (i) and doubly robust moment functions through (ii), in which case Assumption 3 imposes no conditions additional to Assumptions 1 and 2. Conditions (iii) and (iv) are alternative small bias conditions that are only required to hold for  $\hat{\gamma}_\ell$ , and not for  $\hat{\alpha}_\ell$ . Condition (iii) requires a faster than  $n^{-1/4}$  rate for  $\hat{\gamma}$  as is familiar from the semiparametric estimation literature. In many cases, (iii) will be satisfied for the mean-square norm  $\|a\| = \sqrt{E[a(W)^2]}$  so that Assumptions 1–3 will only require mean-square convergence rates.

LEMMA 8: *If Assumptions 1–3 are satisfied, then equation (6.1) is satisfied.*

This key asymptotic result differs from previous results of, for example, Andrews (1994), Newey (1994a), and Chen, Linton, and van Keilegom (2003) in requiring no Donsker conditions. This feature is made possible by the use of cross-fitting in the moment conditions. Avoiding Donsker conditions is important for machine learning first steps that generally do not, or are not known to, satisfy Donsker conditions, as previously discussed in Chernozhukov et al. (2018).

The absence of Donsker conditions helps the conditions of Lemma 8 be much simpler than previous results. The use of orthogonal moment conditions also makes the conditions simpler because they avoid the need to show that

$$\frac{1}{\sqrt{n}} \sum_{\ell=1}^L \sum_{i=1}^n \phi(W_i, \hat{\gamma}_\ell, \alpha_0, \theta_0) \xrightarrow{p} 0, \quad (6.2)$$

which is required for plug-in estimators, as discussed in Appendix C of the Supplemental Material (Chernozhukov, Escanciano, Ichimura, Newey, and Robins (2022)). Showing that this condition is satisfied typically involves substantial calculation that is specific to the estimator  $\hat{\gamma}_\ell$ .

At the same time, Lemma 8 is more general than previous results in applying to any first step estimator, rather than a specific one like the early results of, for example, Robinson (1988), Powell, Stock, and Stoker (1989), and others. Furthermore, all that is required of the first step estimator is mean-square consistency as in Assumption 1 and mean-square rates as in Assumptions 2 and 3. A wide variety of first step estimators will satisfy these conditions, notably machine learners where mean-square consistency and rates have been obtained.

The debiased GMM estimator  $\hat{\theta}$  and Lemma 8 are more complicated in involving construction of and properties for  $\hat{\alpha}_\ell$ . Some such  $\hat{\alpha}_\ell$  is needed in any case for asymptotic variance estimation for a plug-in estimator, which will have the same form as  $\hat{V}$ , so that this feature does not make debiased GMM more complicated than a plug-in estimator for large sample inference.

Lemma 8 shares this generality and simplicity with the asymptotic theory of Chernozhukov et al. (2018). Lemma 8 improves on Chernozhukov et al. (2018) in allowing  $\hat{\alpha}_\ell$  to converge slower than  $n^{-1/4}$  in general, in Assumption 1 applying separately to  $\hat{\gamma}_\ell$  and  $\hat{\alpha}_\ell$ , and having weaker conditions for terms that involve both  $\hat{\gamma}_\ell$  and  $\hat{\alpha}_\ell$  in Assumption 2. These improvements result from Theorem 2 and the structure of orthogonal moments we consider, as the sum of identifying moment functions and the FSIF.

The next condition is useful for consistency of  $\hat{\Psi}$  that appears in the debiased GMM asymptotic variance estimator of equation (2.8).

ASSUMPTION 4:  $\int \|g(w, \hat{\gamma}_\ell, \tilde{\theta}_\ell) - g(w, \hat{\gamma}_\ell, \theta_0)\|^2 F_0(dw) \xrightarrow{p} 0$  and  $\int \|\hat{\Delta}_\ell(w)\|^2 \times F_0(dw) \xrightarrow{p} 0$  for each  $\ell = 1, \dots, L$ .

It is also important to have conditions for convergence of the Jacobian of the identifying sample moments  $\partial \hat{g}(\bar{\theta})/\partial \theta \xrightarrow{p} G = E[\partial g(W, \gamma_0, \theta_0)/\partial \theta]$  for any  $\bar{\theta} \xrightarrow{p} \theta_0$ . To that end, we impose the following condition:

ASSUMPTION 5:  $G$  exists and there is a neighborhood  $\mathcal{N}$  of  $\theta_0$  and  $\|\cdot\|$  such that (i) for each  $\ell$ ,  $\|\hat{\gamma}_\ell - \gamma_0\| \xrightarrow{p} 0$ ; (ii) for all  $\|\gamma - \gamma_0\|$  small enough,  $g(W, \gamma, \theta)$  is differentiable in  $\theta$  on  $\mathcal{N}$  with probability approaching 1 and there are  $C > 0$  and  $d(W, \gamma)$  such that, for  $\theta \in \mathcal{N}$  and  $\|\gamma - \gamma_0\|$  small enough,

$$\left\| \frac{\partial g(W, \gamma, \theta)}{\partial \theta} - \frac{\partial g(W, \gamma, \theta_0)}{\partial \theta} \right\| \leq d(W, \gamma) \|\theta - \theta_0\|^{1/C}; \quad E[d(W, \gamma)] < C.$$

(iii) For each  $\ell = 1, \dots, L, j$ , and  $k$ ,  $\int |\partial g_j(w, \hat{\gamma}_\ell, \theta_0)/\partial \theta_k - \partial g_j(w, \gamma_0, \theta_0)/\partial \theta_k| F_0(dw) \xrightarrow{p} 0$ .

With these conditions in place, the asymptotic normality of semiparametric GMM follows in a standard way.

THEOREM 9: If Assumptions 1–3 and 5 are satisfied,  $\hat{\theta} \xrightarrow{p} \theta_0$ ,  $\hat{Y} \xrightarrow{p} Y$ , and  $G'YG$  is nonsingular, then

$$\sqrt{n}(\hat{\theta} - \theta_0) \xrightarrow{d} N(0, V), \quad V = (G'YG)^{-1} G'Y\Psi YG(G'YG)^{-1}.$$

If also Assumption 4 is satisfied, then  $\hat{V} = (\hat{G}'\hat{Y}\hat{G})^{-1} \hat{G}'\hat{Y}\hat{\Psi}\hat{Y}\hat{G}(\hat{G}'\hat{Y}\hat{G})^{-1} \xrightarrow{p} V$ .

This result and Theorems 10–12 to follow are proven in the Supplemental Material. This result assumes consistency of  $\hat{\theta}$ . In Appendix F, we give primitive conditions for consistency that are like those of this section in using mean-square consistency of first steps. When  $\theta$  and  $g(w, \gamma, \theta)$  have the same dimension, these conditions allow for misspecification where  $\theta_0$  is interpreted as the unique solution to  $E[g(W, \gamma_0, \theta)] = 0$ .

### 6.1. Functionals of NPV

Functionals of a first step satisfying an orthogonality condition  $E[b(X)\lambda(W, \gamma_0)] = 0$  for all  $b \in \mathcal{B}$ , similar to Section 5.3, are of general interest. We give conditions for an identifying moment function  $m(w, \gamma) - \theta$  that includes Example 2. As in Ichimura and Newey (2021), the FSIF has the form  $\alpha(x)\lambda(w, \gamma)$ . Debiased GMM is

$$\hat{\theta} = \frac{1}{n} \sum_{\ell=1}^L \sum_{i \in I_\ell} [m(W_i, \hat{\gamma}_\ell) + \hat{\alpha}_\ell(X_i)\lambda(W_i, \hat{\gamma}_\ell)], \quad \hat{V} = \frac{1}{n} \sum_{\ell=1}^L \sum_{i \in I_\ell} \hat{\psi}_{i\ell}^2,$$

where  $\hat{\psi}_{i\ell} = m(W_i, \hat{\gamma}_\ell) + \hat{\alpha}_\ell(X_i)\lambda(W_i, \hat{\gamma}_\ell) - \hat{\theta}$ . Let  $\bar{\lambda}(X, \gamma) = E[\lambda(W, \gamma)|X]$ ,  $V = \text{Var}(m(W, \gamma_0) + \alpha_0(X)\lambda(W, \gamma_0))$ , and  $\|a\| = \sqrt{\int a(w)^2 F_0(w)}$  denote the mean-square norm.

**THEOREM 10:** If (i)  $E[\lambda(W, \gamma_0)b(X)] = 0$  for all  $b \in \mathcal{B}$  and  $\hat{\alpha}_\ell \in \mathcal{B}$  with probability approaching 1; (ii)  $\alpha_0(X)$  and  $E[\lambda(W, \gamma_0)^2|X]$  are bounded and  $E[m(W, \gamma_0)^2] < \infty$ ; (for  $\ell = 1, \dots, L$ ), (iii)  $\int [m(w, \hat{\gamma}_\ell) - m(w, \gamma_0)]^2 F_0(dw) \xrightarrow{p} 0$ ,  $\int [\lambda(w, \hat{\gamma}_\ell) - \lambda(w, \gamma_0)]^2 F_0(dw) \xrightarrow{p} 0$ ,  $\|\hat{\alpha}_\ell - \alpha_0\| \xrightarrow{p} 0$ ; (iv) either (a)  $\int [\hat{\alpha}_\ell(x) - \alpha_0(x)]^2 [\lambda(w, \hat{\gamma}_\ell) - \lambda(w, \gamma_0)]^2 F_0(dw) \xrightarrow{p} 0$  and  $\sqrt{n}\|\hat{\alpha}_\ell - \alpha_0\|\|\bar{\lambda}(\hat{\gamma}_\ell) - \bar{\lambda}(\gamma_0)\| \xrightarrow{p} 0$ , or (b)  $\sqrt{n}\|\hat{\alpha}_\ell - \alpha_0\|\|\lambda(\hat{\gamma}_\ell) - \lambda(\gamma_0)\| \xrightarrow{p} 0$  and  $\hat{\alpha}_\ell(x)$  in  $\hat{\psi}_{i\ell}$  is replaced by  $\bar{\alpha}_\ell(x) = \hat{\alpha}_\ell(x)1(|\hat{\alpha}_\ell(x)| \leq M) + \text{sgn}(\hat{\alpha}_\ell(x))M1(|\hat{\alpha}_\ell(x)| > M)$  and  $M\|\lambda(\hat{\gamma}_\ell) - \lambda(\gamma_0)\| \xrightarrow{p} 0$ ; (v)  $\sqrt{n}\bar{\psi}(\hat{\gamma}_\ell, \alpha_0, \theta_0) \xrightarrow{p} 0$ , then

$$\sqrt{n}(\hat{\theta} - \theta_0) \xrightarrow{d} N(0, V), \quad \hat{V} \xrightarrow{p} V.$$

## 6.2. Example 2: Functionals of Quantile Regression

We will specify conditions that allow us to apply Theorem 10 to this problem. The next condition will be sufficient for condition (iv) of Theorem 10 for  $\lambda(w, \gamma(x))$  in Section 3.1.

**ASSUMPTION 6:** (i) There exists  $v_m(X)$  in  $\Gamma$  such that  $E[m(W, \gamma)] = E[v_m(X)\gamma(X)]$  for all  $\gamma(X)$  in  $\Gamma$ ; (ii)  $U = Y - \gamma_0(X)$  is continuously distributed and there is  $C > 0$  such that the conditional pdf  $f(u|X)$  of  $U$  conditional on  $X$  satisfies  $C^{-1} \leq f(0|X) \leq C$  and is twice continuously differentiable in  $u$  with probability 1 with  $|\partial^j f(u|X)/\partial u^j| \leq C$  ( $j = 1, 2$ ); (iii)  $\Gamma$  is closed in mean-square.

This condition specifies that  $E[m(W, \gamma)]$  is a mean-square continuous linear functional of  $\gamma$  with Riesz representer  $v_m(X)$  and imposes some restrictions on the conditional pdf of  $U$  given  $X$ . Here  $\alpha_0(X) = \arg \min_{\alpha \in \Gamma} E[f(0|X)\{f(0|X)^{-1}v_m(X) - \alpha(X)\}^2]$  is the linear projection of  $f(0|X)^{-1}v_m(X)$  on  $\Gamma$  weighted by the conditional pdf  $f(0|X)$ . The  $\hat{\alpha}_\ell(X)$  given in Section 3 will estimate  $\alpha_0(X)$  because weighting by  $f(0|X)$  is incorporated in the kernel weighting included in  $\hat{Q}_\ell$ . This weighting allows us to avoid inverting an estimator of  $f(0|X)$ . We obtain a mean-square convergence rate for this  $\hat{\alpha}_\ell(x)$  by extending the results of Chernozhukov, Newey, and Singh (2018) to allow kernel weighting in  $\hat{Q}_\ell$ . Because this paper is focused on the properties of  $\hat{\theta}$ , we reserve the full conditions to Appendix D of the Supplemental Material, only stating here the conditions required of the kernel  $K(u)$ , the bandwidth  $h$ , and the regularization factor  $r$  in the Lasso minimum distance estimator in equation (3.2). This condition will require that  $r$  shrinks slower than the usual Lasso rate.

**ASSUMPTION 7:** (i)  $K(u)$  is a symmetric bounded kernel of order  $\kappa$  with bounded support; (ii)  $h\sqrt{n} \rightarrow \infty$ ; (iii) for each  $\ell, \ell'$ ,  $\|\hat{\gamma}_{\ell\ell'} - \gamma_0\| = O_p(n^{-d_\gamma})$ ; (iv)  $\sqrt{\ln(p)/(hn)} + h^2 + n^{-d_\gamma} = o(r)$ ; (v)  $r \rightarrow 0$ ; (vi) there is  $C > 0$  such that  $|m(W, b_j)| \leq C$  for all  $j$ .

The following result gives conditions for asymptotic inference for the estimator of a linear functional of a regression quantile estimator.

**THEOREM 11:** If (i) Assumptions 6 and 7 are satisfied; (ii)  $E[m(W, \gamma_0)^2] < \infty$  and  $\int [m(w, \hat{\gamma}_\ell) - m(w, \gamma_0)]^2 F_0(dw) \xrightarrow{p} 0$ ; (iii)  $\|\hat{\gamma}_\ell - \gamma_0\| = O_p(n^{-d_\gamma})$  for  $1/4 < d_\gamma < 1/2$ ; either (iv) Assumption D1 is satisfied and  $\sqrt{n}\sqrt{r}n^{-d_\gamma} \rightarrow 0$  or (v) Assumptions D1, D3, and D4 are satisfied and  $\sqrt{nr}^{2\xi/(1+2\xi)}n^{-d_\gamma} \rightarrow 0$ ; and (vi)  $v_m(X)$  and  $\alpha_0(X)$  are bounded, then

$$\sqrt{n}(\hat{\theta} - \theta_0) \xrightarrow{d} N(0, V), \quad \hat{V} \xrightarrow{p} V.$$

This result depends on the regression quantile estimator converging at a mean-square rate that is faster than  $n^{-1/4}$ . Such a rate for an  $L_1$  regularized regression quantile estimator was derived by Belloni and Chernozhukov (2011).

### 6.3. Example 3: Dynamic Discrete Choice

A result that is important for the properties of  $\hat{\theta}$  for dynamic discrete choice and more generally for economic structural models is a convergence rate for the estimator  $\hat{\gamma}_2(x)$  of the value function term in the choice probability. We maintain independence of observations across  $i$  but allow arbitrary dependence across  $t$ .

ASSUMPTION 8: (i) There is  $\varepsilon > 0$  such that  $\gamma_{10}(X) \in [\varepsilon, 1 - \varepsilon]$ , for all  $\ell, \ell', \hat{\gamma}_{1\ell\ell'}(X_t) \in [\varepsilon, 1 - \varepsilon]$ , and  $H(p)$  is twice continuously differentiable on  $[\varepsilon, 1 - \varepsilon]$ ; (ii) for all  $\ell, \ell', \|\hat{\gamma}_{1\ell\ell'} - \gamma_0\| = O_p(n^{-d_1})$ ,  $0 < d_1 < 1/2$ ; (iii) Assumptions D1 - D4 are satisfied with  $\alpha_0(x) = \gamma_{20}(x)$ ,  $\varepsilon_n = n^{-d_1}$ , and sparse approximation rate  $\xi_1 > 1/2$ ; (iv)  $n^{-d_1} = o(r_1)$  and  $r_1 = O(n^{-d_1} \ln(n))$ .

This Assumption is sufficient for a uniform convergence rate of the estimator  $\hat{\gamma}_2(x)$  as in Lemma E6 of Appendix E. In practice, condition (i) requires fixed trimming where  $\hat{\gamma}_{1\ell\ell'}(X_t)$  is censored below by  $\varepsilon$  and above by  $1 - \varepsilon$ , with  $\varepsilon$  being known. Here and in Theorem 12 below, we impose tighter restrictions on the penalty sizes  $r_1$ ,  $r_2$ , and  $r_3$  than needed in order to allow smaller sparse approximation rates, for example,  $\xi_1$  in Assumption 8.

THEOREM 12: If (i) Assumption 8 is satisfied, (ii)  $\Lambda(a) > 0$  for all  $a \in \mathfrak{R}$ ,  $\ln \Lambda_a(a)$  is concave,  $\Lambda(a)$  is twice differentiable with uniformly bounded derivatives,  $D(x)$  is bounded,  $E[D(X)D(X)']$  is nonsingular; (iii) Assumptions D1, D3, and D4 are satisfied for  $\alpha_0(x)$  equal to each element of  $E[D(X_t)\pi(a_0(X_t))\Lambda_a(a(X_t)Y_{2t}/\Lambda(a(X_t))|X_{t+1}=x]$  with sparse approximation rate  $\xi_2$  and for  $E[Y_{1t}|X_{t+1}=x]$  with sparse approximation rate  $\xi_3$ ; and (iv)  $d_1 > 1/4$ ; (v)  $1 + [(2\xi_1 - 1)/(2\xi_1 + 1)]2\xi_2/[2\xi_2 + 1] > 1/2d_1$ ,  $n^{-d_1(2\xi_1-1)/(2\xi_1+1)} = o(r_2)$ , and  $r_2 = O(n^{-d_1(2\xi_1-1)/(2\xi_1+1)} \ln(n))$ ; (vi)  $\xi_3/[2\xi_3 + 1] + d_1 > 1/2$ ,  $\sqrt{\ln(p)/n} = o(r_3)$ , and  $r_3 = O(\sqrt{\ln(p)/n} \ln(n))$ ; (vii)  $(4\xi_1 - 1)/(2\xi_1 + 1) > 1/2d_1$ , then, for  $V = G^{-1}E[\psi_0(W)\psi_0(W)']G^{-1}$ ,

$$\sqrt{n}(\hat{\theta} - \theta_0) \xrightarrow{d} N(0, V), \quad \hat{V} \xrightarrow{p} V.$$

## APPENDIX A: PROOFS OF KEY RESULTS

PROOF OF THEOREM 1: Let  $\phi(w, F_\tau) := \phi(w, \gamma(F_\tau), \alpha(F_\tau), \theta)$ . By (ii),

$$0 = (1 - \tau) \int \phi(w, F_\tau) F_0(dw) + \tau \int \phi(w, F_\tau) H(dw).$$

Dividing by  $\tau$  and solving gives

$$\frac{1}{\tau} \int \phi(w, F_\tau) F_0(dw) = - \int \phi(w, F_\tau) H(dw) + \int \phi(w, F_\tau) F_0(w).$$

Taking limits as  $\tau \rightarrow 0$ ,  $\tau > 0$  it follows by (iii) that

$$\begin{aligned} \frac{1}{\tau} \int \phi(w, F_\tau) F_0(dw) &\rightarrow - \int \phi(w, F_0) H(dw) + 0 \\ &= - \int \phi(w, F_0) H(dw). \end{aligned} \quad (\text{A.1})$$

By (ii), we have  $\int \phi(w, F_0) F_0(dw) = 0$ , so that  $\int \phi(w, F_\tau) F_0(dw)$  is differentiable in  $\tau$  from the right at  $\tau = 0$  and

$$\frac{d}{d\tau} \int \phi(w, F_\tau) F_0(dw) = - \int \phi(w, F_0) H(dw) = - \frac{d}{d\tau} \int g(w, \gamma(F_\tau), \theta) F_0(dw),$$

where the last equality follows by (i). Adding  $d \int g(w, \gamma(F_\tau), \theta) F_0(dw) / d\tau$  to both sides of this equation gives equation (4.1). *Q.E.D.*

**PROOF OF THEOREM 2:** Since  $\gamma(F_\tau^\alpha) = \gamma_0$  is a constant, hypothesis (ii) implies that

$$\begin{aligned} E[\phi(W, \gamma_0, \alpha, \theta)] &= \int \phi(w, \gamma_0, \alpha, \theta) F_0(dw) \\ &= d \int g(w, \gamma(F_\tau^\alpha), \theta) F_\alpha(dw) / d\tau \\ &= d \int g(w, \gamma_0, \theta) F_\alpha(dw) / d\tau = 0. \end{aligned} \quad \text{Q.E.D.}$$

**PROOF OF THEOREM 3:** By (ii), the chain rule for Hadamard derivatives (see 20.9 of [van der Vaart \(1998\)](#)), and by equation (4.1), it follows that for  $\delta_H = d\gamma(F_\tau) / d\tau$ ,

$$\bar{\psi}_\gamma(\delta_H, \alpha_0, \theta_0) = \frac{\partial \bar{\psi}(\gamma(F_\tau), \alpha_0, \theta)}{\partial \tau} = 0.$$

Equation (4.3) follows by  $\bar{\psi}_\gamma(\delta, \alpha_0, \theta_0)$  being a continuous linear function and (iii). Equation (4.4) follows by Proposition 7.3.3 of [Luenberger \(1969\)](#). *Q.E.D.*

**PROOF OF THEOREM 4:** Suppose that  $\psi(w, \gamma, \alpha, \theta)$  is doubly robust. Then, for any  $\delta \in \Gamma$  and any  $t$ , it follows that  $\gamma_0 + t\delta \in \Gamma$  so that

$$\bar{\psi}(\gamma_0 + t\delta, \alpha_0, \theta) = \bar{\psi}(\gamma_0, \alpha_0, \theta),$$

identically in  $t$ . Differentiating with respect to  $t$  gives  $d\bar{\psi}(\gamma_0 + t\delta, \alpha_0, \theta) / dt = 0$ . Also,  $\bar{\psi}(\gamma, \alpha_0, \theta)$  is constant as a function of  $\gamma$  and so is affine. Now suppose that  $\bar{\psi}(\gamma, \alpha_0, \theta)$  is affine in  $\gamma$ . Then for any  $t$ ,

$$\begin{aligned} \bar{\psi}(\gamma_0 + t(\gamma - \gamma_0), \alpha_0, \theta) &= \bar{\psi}((1-t)\gamma_0 + t\gamma, \alpha_0, \theta) \\ &= (1-t)\bar{\psi}(\gamma_0, \alpha_0, \theta) + t\bar{\psi}(\gamma, \alpha_0, \theta) \\ &= \bar{\psi}(\gamma_0, \alpha_0, \theta) + t[\bar{\psi}(\gamma, \alpha_0, \theta) - \bar{\psi}(\gamma_0, \alpha_0, \theta)]. \end{aligned}$$

It then follows from  $d\bar{\psi}(\gamma_0 + t\delta, \alpha_0, \theta)/dt = 0$  for  $\delta = \delta - \delta_0 \in \Gamma$  that

$$0 = \frac{d}{dt} \bar{\psi}(\gamma_0 + t(\gamma - \gamma_0), \alpha_0, \theta) = \bar{\psi}(\gamma, \alpha_0, \theta) - \bar{\psi}(\gamma_0, \alpha_0, \theta),$$

that is, that  $\bar{\psi}(\gamma, \alpha_0, \theta) = \bar{\psi}(\gamma_0, \alpha_0, \theta)$ .

*Q.E.D.*

**PROOF OF THEOREM 5:** By orthogonality of least squares residuals,  $E[\alpha_0(X)\{Y - \gamma_0(X)\}] = 0$ , so that

$$\begin{aligned} \bar{\psi}(\gamma, \alpha_0, \theta) &= E[m(W, \gamma)] - \theta + E[\alpha_0(X)\{Y - \gamma(X)\}] \\ &= E[\alpha_0(X)\gamma(X)] - \theta + E[\alpha_0(X)\gamma_0(X)] - E[\alpha_0(X)\gamma(X)] \\ &= \theta_0 - \theta. \end{aligned}$$

*Q.E.D.*

**PROOF OF THEOREM 6:** By (i), (ii), (iii), iterated expectations, and  $\text{proj}_{F_0}(\gamma(Z)|\mathcal{B}) \in \mathcal{A}$ , for all  $\gamma \in \Gamma$ ,

$$\begin{aligned} E[m(W, \gamma)] &= E[v_m(Z)\gamma(Z)] \\ &= E[\text{proj}_{F_0}(b_m(X)|\Gamma)\gamma(Z)] \\ &= E[b_m(X) \text{proj}_{F_0}(\gamma(Z)|\mathcal{B})] \\ &= E[\alpha_0(X) \text{proj}_{F_0}(\gamma(Z)|\mathcal{B})] \\ &= E[\alpha_0(X)\gamma(Z)]. \end{aligned}$$

Therefore, for  $\tilde{\gamma} = \gamma - \gamma_0$ , it follows by  $E[\alpha_0(X)\{Y - \gamma(Z)\}] = -E[\alpha_0(X)\tilde{\gamma}(Z)]$  that

$$\begin{aligned} \bar{\psi}(\gamma, \alpha_0, \theta) &= E[m(W, \gamma)] - \theta + E[\alpha_0(X)\{Y - \gamma(Z)\}] \\ &= E[m(W, \tilde{\gamma})] - \theta + \theta_0 - E[\alpha_0(X)\tilde{\gamma}(Z)] = -\theta + \theta_0. \end{aligned}$$

*Q.E.D.*

**PROOF OF THEOREM 7:** For  $\tilde{\gamma} = \gamma - \gamma_0$ ,

$$\begin{aligned} \bar{\psi}(\gamma, \alpha_0, \theta) &= E[m(W, \gamma)] - \theta + E[\alpha_0(X)] - \int \alpha_0(u)\gamma(u) du \\ &= \theta_0 - \theta + \int \alpha_0(u)\{\gamma(u) - \gamma_0(u)\} du + \int \alpha_0(u)\{\gamma_0(u) - \gamma(u)\} du \\ &= \theta_0 - \theta. \end{aligned}$$

*Q.E.D.*

**PROOF OF LEMMA 8:** Define

$$\begin{aligned} \hat{R}_{1\ell i} &:= g(W_i, \hat{\gamma}_\ell, \theta_0) - g(W_i, \gamma_0, \theta_0), \\ \hat{R}_{2\ell i} &:= \phi(W_i, \hat{\gamma}_\ell, \alpha_0, \theta_0) - \phi(W_i, \gamma_0, \alpha_0, \theta_0), \\ \hat{R}_{3\ell i} &:= \phi(W_i, \gamma_0, \hat{\alpha}_\ell, \hat{\theta}_\ell) - \phi(W_i, \gamma_0, \alpha_0, \theta_0), \quad i \in I_\ell. \end{aligned} \tag{A.2}$$

Then, for  $\hat{\Delta}_\ell(W_i)$  as in Assumption 2, we have

$$\begin{aligned} g(W_i, \hat{\gamma}_\ell, \theta_0) + \phi(W_i, \hat{\gamma}_\ell, \hat{\alpha}_\ell, \tilde{\theta}_\ell) - \psi(W_i, \gamma_0, \alpha_0, \theta_0) \\ = \hat{R}_{1\ell i} + \hat{R}_{2\ell i} + \hat{R}_{3\ell i} + \hat{\Delta}_\ell(W_i). \end{aligned} \quad (\text{A.3})$$

Let  $\mathcal{W}_\ell^c$  denote the observations not in  $I_\ell$ , so that  $\hat{\gamma}_\ell$ ,  $\hat{\alpha}_\ell$ , and  $\tilde{\theta}_\ell$  depend only on  $\mathcal{W}_\ell^c$ . Therefore, by  $0 = E[g(W, \gamma_0, \theta_0)] = E[\phi(W, \gamma_0, \alpha_0, \theta_0)]$  and Assumption 3(i) (which comes from Theorem 2),

$$\begin{aligned} E[\hat{R}_{1\ell i} + \hat{R}_{2\ell i} | \mathcal{W}_\ell^c] &= \int [g(w, \hat{\gamma}_\ell, \theta_0) + \phi(w, \hat{\gamma}_\ell, \alpha_0, \theta_0)] F_0(dw) \\ &= \bar{\psi}(\hat{\gamma}_\ell, \alpha_0, \theta_0), \\ E[\hat{R}_{3\ell i} | \mathcal{W}_\ell^c] &= \int \phi(w, \gamma_0, \hat{\alpha}_\ell, \tilde{\theta}_\ell) F_0(dw) = 0. \end{aligned} \quad (\text{A.4})$$

Then by Assumption 3,

$$\begin{aligned} \left\| \frac{1}{\sqrt{n}} \sum_{i \in I_\ell} E[\hat{R}_{1\ell i} + \hat{R}_{2\ell i} + \hat{R}_{3\ell i} | \mathcal{W}_\ell^c] \right\| &= \frac{n_\ell}{\sqrt{n}} \|\bar{\psi}(\hat{\gamma}_\ell, \alpha_0, \theta_0)\| \\ &\leq \sqrt{n} \|\bar{\psi}(\hat{\gamma}_\ell, \alpha_0, \theta_0)\| \xrightarrow{p} 0. \end{aligned} \quad (\text{A.5})$$

Also, by observations in  $I_\ell$  mutually independent conditional on  $\mathcal{W}_\ell^c$  and Assumption 1,

$$\begin{aligned} E\left[\left\{\frac{1}{\sqrt{n}} \sum_{i \in I_\ell} (\hat{R}_{j\ell i} - E[\hat{R}_{j\ell i} | \mathcal{W}_\ell^c])\right\}^2 \middle| \mathcal{W}_\ell^c\right] &= \frac{n_\ell}{n} \text{Var}(\hat{R}_{j\ell i} | \mathcal{W}_\ell^c) \\ &\leq E[\hat{R}_{j\ell i}^2 | \mathcal{W}_\ell^c] \xrightarrow{p} 0 \quad (j = 1, 2, 3). \end{aligned}$$

Then by the triangle and conditional Markov inequalities,

$$\frac{1}{\sqrt{n}} \sum_{i \in I_\ell} (\hat{R}_{1\ell i} + \hat{R}_{2\ell i} + \hat{R}_{3\ell i} - E[\hat{R}_{1\ell i} + \hat{R}_{2\ell i} + \hat{R}_{3\ell i} | \mathcal{W}_\ell^c]) \xrightarrow{p} 0. \quad (\text{A.6})$$

By equations (A.5) and (A.6) and the triangle inequality,  $\sum_{i \in I_\ell} (\hat{R}_{1\ell i} + \hat{R}_{2\ell i} + \hat{R}_{3\ell i}) / \sqrt{n} \xrightarrow{p} 0$ . It also follows from Assumption 2(i) similarly to equation (A.6), or Assumption 2(ii) by the triangle inequality, or just by Assumption 2(iii), that  $\sum_{i \in I_\ell} \hat{\Delta}_{\ell i}(W_i) / \sqrt{n} \xrightarrow{p} 0$ . The conclusion then follows by the triangle inequality and equation (A.3). Q.E.D.
